Summary

Abstract

History of fruit tree cultivation in Sardinia seems to be dated from the Bronze Age and during the Phoenician-Punic period (Agabbio et al., 2015; Ucchesu et al., 2015). Many fruits were collected for human consumption as a fig, plum, grape, olive, almond and hazelnuts (Condit, 1947; Ucchesu et al., 2014; Sarigu et al., 2016). The long tradition of the cultivation of fruit trees in Italy has created over time a genetic biodiversity that currently is disappearing because of their substitution with new, more productive varieties. However, to avoid the loss of genetic diversity these they must be are properly maintained (Choen et al., 1991).

For Sardinia, the protection of biodiversity of wild and domesticated fruit species with limited diffusion is even more justified in that they represent a gene pool for the long geographical isolation and genetic shows great interest for research not only in Italy (Agabbio et al., 2015). The old varieties have been almost excluded from the orchards because of their low productivity, which in many cases did not have met the standards of modern varieties.

The fruit germplasm of Italian varieties is an important resource of genetic diversity that can be used in addition characterizations for the germplasm collections of European, to optimize the efficiency of the association studies within the genome and to identify genomic regions control the main horticultural characteristics (Liang et al., 2015).

Presently for the preservation of ancient varieties in Italy, there are different catalogue fields where the characteristics of these ancient varieties are preserved and studied both from the genotype and the phenotypic point of view.

PhD structure

My PhD research was focused on the study of characterisation and comparison different Sardinian varieties of *Malus* and *Pyrus* throught morphometric and genetic analyses.
This research is divided in four chapter:

Chapter 1: we present the results of a study conducted on 25 Sardinian varieties of *Malus domestica* for investigating the possible existence a relationship between seed morphology and apple skin colour.
The main goals of this work are to:
(1) build a descriptive morphometric database of Sardinian apple seeds, useful for classifying the phenotypic characteristics;
(2) investigated the relationship between seed morphology and fruit skin colour.

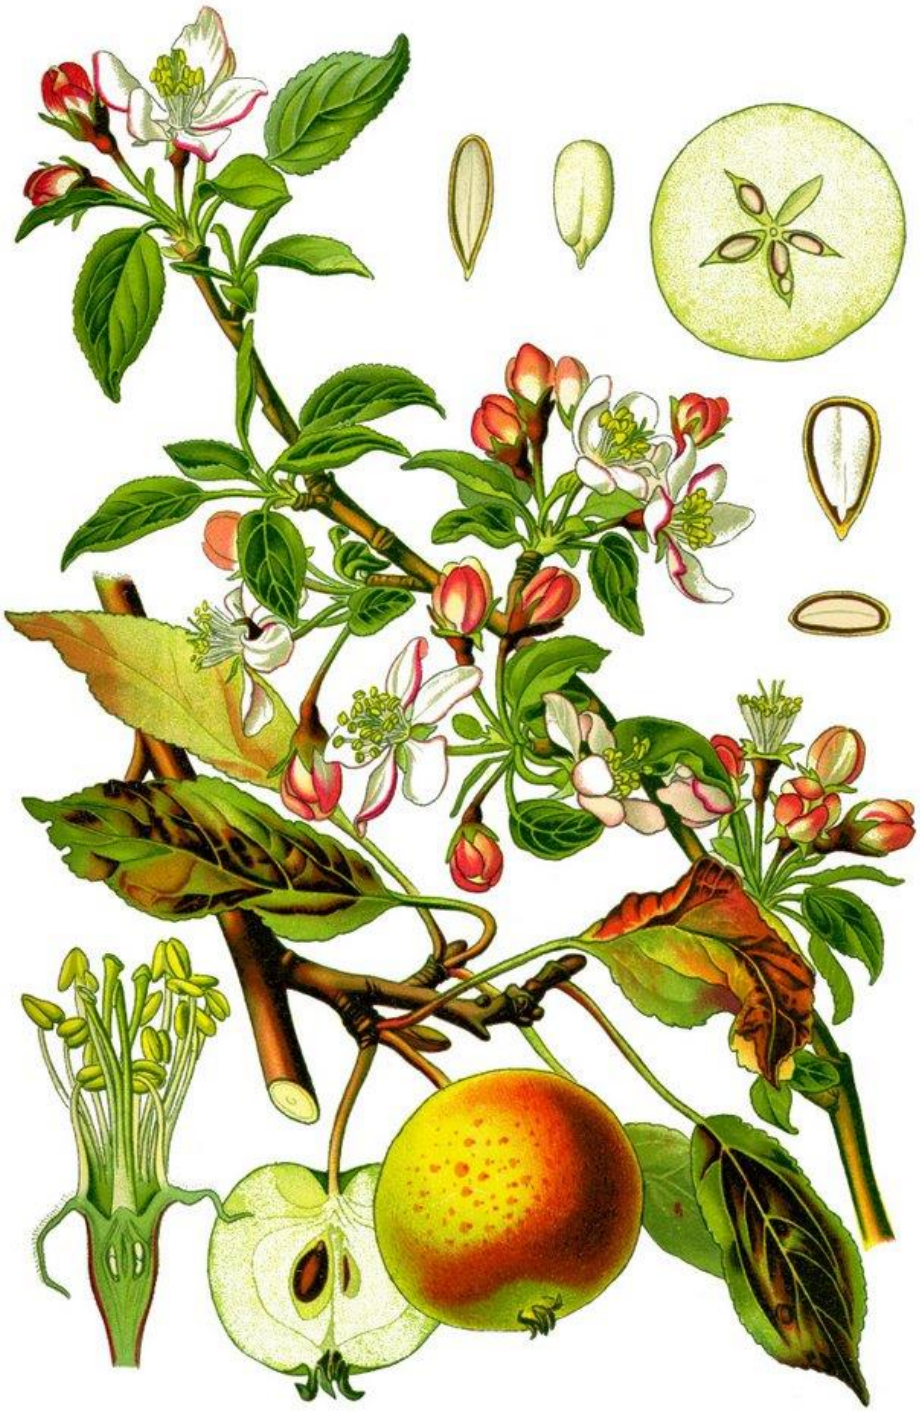
Chapter 2: we evaluate the trustworthiness of seed image analysis as an approach to discriminate apple germplasm accessions.
The main goals of this work were to:
(1) build a database of seed morphological variables of apple cultivars, suitable for variety characterization;
(2) assess the phenotypic diversity of apples by morphological seed image analysis techniques and by LDA;
(3) compare our seed image analysis data with a genetic study previously conducted on the same varieties (Liang et al., 2015).

Chapter 3: we present the result of study for investigating the relationship between *Pyrus communis* and *P.spinosa* and the phenomenon of over-ripening in Sardinian *P. communis* varieties. In this study, we compared 65 Sardinian varieties of *P. communis* with 44 international varieties and 7 Sardinian varieties of *P. spinosa*.
The main goals of this study are to investigate by seed image analysis the phenotype diversity of pears, in particular:
(1) the relationship between local cultivars and wild populations of Sardinian pear and national and international varieties;
(2) the phenomenon of pear over-ripening in Sardinian local cultivars.

Chapter 4: we present a **c**haracterization of microsatellite loci in Sardinian pears (*Pyrus communis* L. and *Pyrus spinosa* Forssk.).

The aim of the present study was to estimate the genetic relationship among wild and local pear varieties from Sardinia and national and international ones, using SSR markers. This molecular characterization will: identify the genetic diversity; investigate cases of homonymous and/or synonymous genotypes that are difficult to distinguish using standard morphological descriptors and increase the *Pyrus* molecular marker datasets.

The species *Malus domestica* Borkh.



1. Botanical description

Domestic apple (*Malus domestica* Borkh.) belongs to the great family of Rosaceae, which includes different forms with closely related fruits such as the *Pyrus* and *Cydonia* genera and ornamental genres such as *Amelanchier*, *Aronia*, *Chaenomeles*, *Cotoneaster*, *Crataegus*, *Pyracantha* and *Sorbus* (Challice, 1974).

The difficulty in delimiting species within the genus has been widely investigated (Korban, 1986; Rohrer et al., 1994; Robison et al., 2001). The morphological characters used to delineate *Malus* species and subspecies change continuously and in some cases overlap, contradicting each other (Harris et al., 2002; Hummer and Janick, 2009).

The genus *Malus* possesses pentamers flowers, with tubular cavities, do not open at the top and completely included carpels, which are a number of 3-5 and connected with the hypanthium, with cartilaginous walls in the fruit, each of which contains two or more ovules. From the carpels and the hypanthium, develop a fake fruit (pomo) more or less globally (Pignatti, 1982). The baseline chromosomal number is n = 17, while ploidy levels may be variable (from haploid to triploid). It includes about 55 species, distributed throughout the boreal hemisphere. Of them, only some have crop interest as fruit plants. Others are cultivated for ornamental purposes, for flowers and abundant and vibrantly colorful fruits.

2. Origin

Domestic apple is one of the world's most important fruit cultivars in terms of production level (FAOSAT 2014) and occupies a central position in culture, folklore and art of many populations.

The culture of apple is known to the Greeks end italics already in the early stages of their social development, at least from 800 BC Greek and Latin texts talk about it widely.

Moreover, the study conducted by Vavilov suggests that Turkestan wild apple and close relatives represented the progeny of domesticated apple, and see it as the centre of domestication origin of this Almaty in Kazakhstan (Forsline, 1995). Vavilov believed that the wild apple had similar fruits to the home apple could have had the same progenitor. Moreover, Janick and Moree's work (1996) confirmed that the area considered by Vavilov represents the area of greater biodiversity and the centre of origin of the domestic apple. With the passage of time humans began to occupy the area about 5000-8000 years ago, the first evolution of the apple was almost complete, and its migration was skillfully assisted by the use of domesticated horses.

Over several thousand years, within this migration flow, the many thousands of apple cultivars have come notes to date, as a result of unconscious and conscious selection.

Moreover, based on archaeological data combined with the molecular ones, it seems likely that in the late Neolithic or early Bronze Age, travelers on the major commercial routes from central China to the Danube transported the seed of Western Asia's wild apple, in handbags or bowels of horses (Crosby, 2007).

At present we know that the technique of grafting described as taming by Teofrasto (323 BC) was indispensable to optimize production, and how direct sowing normally yielded inferior quality fruits

Two stages seem to have been important in the domestication of apples; the initial introduction of apples in Western Europe and subsequently the hybridizations between cultivar and between cultivars and wild species (Zohari, 1991).

Morphology, biochemical, and molecular variation within wild apples indicate that the first selection of tamed apples could originate directly from their natural environment without the involvement of other species (Crosby, 2007). However, subsequent hybridization could have been important in creating new cultivars that carry economically important features. These analyses would require better research and sampling of cultivar varieties in Central Asia.

Central Asia currently represents a very important centre of diversity of wild apples that are distinguished by colour, taste and shape.

In the 1920s, Vavilov (1930) travelled through central Asia and reported that *M.sieversii*'s great wild specimens existed in specific locations and suggested the region as the centre of origin for domesticated apple (Janick, 2003).

Dzhangaliev (1977), confirmed the existence of wild apple forests at the time, also noted that they were under pressure in some areas due to urbanization, agriculture, fodder and wood harvesting.

The man has exploited this fruit for centuries by selecting it and giving birth to several thousands of documented cultivars. Numerous genetic studies have been carried out over the last decades in order to evaluate the origin of cultivars (Harris et al., 2002).

Studies on the variability of genetically informative traits were dealt with using different molecular biology techniques that were designed not only to determine the characteristic traits of the genome of each cultivar but also to identify progenitors.

Among the most widely used molecular biology techniques are those based on the study of restriction fragments (RFLPs), amplified fragment lengths (AFLPs), satellite DNA (SSR) or sequencing of genome traits, also used for the analysis of fruit trees (Coart et al., 2006).

The use of these methodologies implies a comparative study in order to choose the genome marker (nuclear or plastid) that best suits the needs of the operator.

All of these studies have been dealt with in the program of conservation of the genome of apple tree varieties in order to provide information on abandoned old varieties with good organoleptic characteristics, resistance to disease and therefore useful to provide native genetic resources to exploit also commercial purposes.

Most authors concur that the apple cultivars derive from *Malus pumila* (Heywood and Zohary, 1995) or from crosses between the latter and other species, such as *Malus sieversii* (Mill.), *M. orientalis* (Uglitzk.) and *M. sylvestris* (Mill.), all from Europe or Asia (Forsline et al., 2003). Clearly, there is still much to discover about the origin of apple domestication, the processes that led to its domestication and the origins of both desserts and cider apples.

3. Economic importance

M. domestica is the most important species from the economic point of view of the Rosaceae family, with world production of 84,630,275 tons (www.fao.org/faostat/en/#compare).

The popularity of apple is due to the fact that the fruit has many uses. It can be consumed fresh or preserved for months, while a large percentage of the crop is converted into sauces, juices, cider, pectin vinegar and baked goods. Winter apples, harvested in late autumn and stored at higher temperatures than freezing, are considered an important food in Europe, Asia, Argentina and the United States. The fruit has a low-calorie content and contains vitamin C. Some studies suggest that apples can help slow down the development of cancer, manage diabetes, and help patients prepare for surgery (Gossè et al., 2004).

In addition, other studies have shown that antioxidants contained in apples can protect nerve cells from diseases such as Alzheimer's and Parkinson's (Boyer et al., 2004).

However, further research is needed to confirm these results.

CHAPTER 1: Relationship between seeds morphology and skin colour of Sardinian apple cultivars.

1. Introduction

The genus *Malus* (Rosaceae) includes about 55 species mainly distributed in temperate regions (Cornille et al., 2012). The domesticated apple (*Malus domestica* Borkh.) is one of the most important fruit crops in terms of production levels (http://faostat.fao.org/).

The origin of apple domestication is still remained unknown due to his out-crossing, self-incompatibility and also because of the genus *Malus* capacity to hybridize itself and to generate highly variable progenies (Zohary et al., 2012; Cornille et al., 2012; Velasco et al., 2010).

In addition, morphological characters used to delimit species and subspecies in genus *Malus* are continuous and overlapping, making it difficult to effectively understand the exact number of this genus (Robison et al., 2001). Recent, genetic studies have allowed us to hypothesize that domestic apple is derived from *M. sieversii* and *M. roem* (Velasco et al., 2010; Cornille et al., 2012).

Today, there are over 10,000 varieties of apples with different variations in fruit skin colour and taste of the pulp (Harris et al., 2002; Cornille et al., 2012, 2014).

In Italy, the germplasm fruit collections is an important genetic resource that can be used for breeding program and for investigating genomic regions that control the main horticultural characteristics (Liang et al., 2015). In this way, the use of the molecular markers plays an important role determining apple biodiversity relationships, which can clear away from the frequent synonyms and homonyms within specific germplasm collections (Velasco et al., 2010; Cornille et al., 2012; Liang et al., 2015; Urrestarazu et al., 2012, 2016).

In the case of Sardinia, although the cultivation of apple is not very widespread, there is a considerable number of old varieties with excellent organoleptic characteristics. Currently, these old apple varieties have been almost excluded from the orchards because of their low productivity and stored in several catalogues of fields (Agabbio et al., 2015).

Among the different phenotypic traits for commercial interest, apple skin colour plays a very crucial role on the way to capture the attention of the consumers giving a significantly influence the market value (Kim et al., 2003). Apple skin colour is an important quality indicator that influence consumer acceptance, with a strong increase for red skin cultivars. This trend influences directly the growers and is becoming a very important goal in breeding programs (Velasco et al., 2010; Bi et al., 2014).

The class of flavonoids represents a fundamental role in the coloring of apple skin, in particular from anthocyanins that are responsible for the red colour but also for other variants of coloring

(Lancaster and Dougall, 1992). In fact, anthocyanins with chlorophyll and carotenoids determine the colour variation in apple skin (Honda et al., 2002). Several studies have established that in some apple cultivars high levels of anthocyanins are accumulated especially in red apples (White and Lespinasse, 1986; Honda et al., 2002; Kim et al., 2003; Ubi, 2004; Jaakola, 2013).

In apple, an R2R3 MYB transcription factor has been shown to control the pigmentation of the pulp and leaf anthocyanins (MYB10) and (MYB1) the fruit skin colour (Chagnè et al., 2007; Honda et al., 2002).

Over the last 20 years, the use of seed image analysis through Linear Discriminant Analysis (LDA) application has allowed characterising different cultivars such as *Vitis vinifera* subsp. *vinifera* L., *Olea europaea* L., *Prunus domestica* L., *Cucumis melo* L. (Orrù et al., 2012, 2013; Sabato et al., 2015; Piras et al., 2016).

In order to identify multiple variables measured on multiple samples multivariate statistical analysis could be very useful. Multivariate data contain much more information than univariate analysis. Multivariate data analysis techniques can be used to model factors and responses and find the relationship that exists between them. Information resulted from multivariate data are usually very helpful to understand the characteristics of different systems and processes (Zude et al. 2003; Perk et al., 2010; Caboni et al., 2017; Murgia et al., 2016).

In this paper, the relationship between the seeds morphology and the apple skin colour be analysed by seed image analysis and data processed by Linear Discriminant Analysis (LDA) and Principal Component Analysis (PCA).

The main goals of this work are to:

(1) build a descriptive morphometric database of Sardinian apple seeds, useful for classifying the phenotypic characteristics;

(2) investigated the relationship between seed morphology and fruit skin colour.

2. Material and Methods

2.1. Apple varieties

In this work 25 traditional Sardinia, apple varieties were investigated using seed image analysis. The germplasm varieties were collected in the field catalogue of CNR-ISPA (Nuraxinieddu, Oristano, Sardinia) (Table 1). The fruits were harvested at full maturity, after removing the pulp, the seeds were cleaned and washed, and dried at room temperature, following the manual of standard procedures adopted in the Germplasm Bank of Sardinia BG-SAR (Atzeri et al., 2012).

Table 2. List of the 26 morphometric seed features measured on endocarps and calculated by Particles8 plugins from ImageJ v. 1.49.

Parameter	Description
Perim	Perimeter, calculated from the centres of the boundary pixels
Area	Area inside the polygon defined by the perimeter
Pixels	Number of pixels forming the seed image
MinR	Radius of the inscribed circle centred at the middle of mass
MaxR	Radius of the enclosing circle centred at the middle of mass
Feret	Larges taxis length
Breadth	Largest axis perpendicular to the Feret
CHull	Convex hull or convex polygon calculated from pixel centres
CArea	Area of the convex hull polygon
MBCRadius	Radius of the minimal bounding circle
AspRatio	Aspect ratio = Feret/Breadth
Circ	Circularity = $4 \cdot \pi \cdot \text{Area}/\text{Perimeter}^2$
Roundness	Roundness = $4 \cdot \text{Area}/(\pi \cdot \text{Feret}^2)$
ArEquivD	Area equivalent diameter = $\sqrt{((4/\pi) \cdot \text{Area})}$
PerEquivD	Perimeter equivalent diameter = Area/π
EquivEllAr	Equivalent ellipse area = $(\pi \cdot \text{Feret} \cdot \text{Breadth})/4$
Compactness	Compactness = $\sqrt{((4/\pi) \cdot \text{Area})}/\text{Feret}$
Solidity	Solidity = Area/Convex_Area
Concavity	Concavity = Convex_Area-Area
Convexity	Convexity = Convex_hull/Perimeter
Shape	Shape = $\text{Perimeter}^2/\text{Area}$
RFactor	RFactor = Convex_Hull /$(\text{Feret} \cdot \pi)$
ModRatio	Modification ratio = $(2 \cdot \text{MinR})/\text{Feret}$
Sphericity	Sphericity = MinR/MaxR
ArBBox	Area of the bounding box along the feret diameter = Feret·Breadth
Rectang	Rectangularity = Area/ArBBox

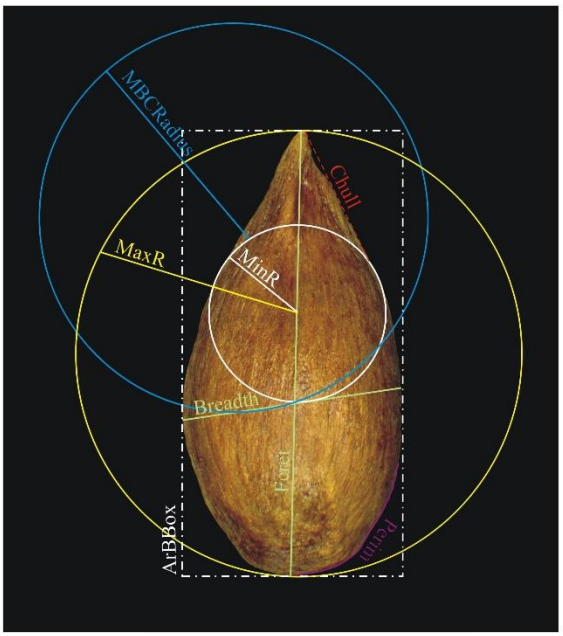

Fig 1. Graphical representation of principal morphometric parameters measured on each seed. Sample details are reported in Table 2.

2.2.2. Seed image analysis

The digital images of seeds were acquired using a flatbed scanner (Epson Perfection V550), with a digital resolution of 800 dpi for a scanning area not exceeding 1024×1024 pixels (Bacchetta et al., 2008). Digital images of seeds were processed and analyzed using the software package ImageJ v. 1.49 (http://rsb.info.nih.gov/ij). A plugin, Particles8, freely available on the official website (http://www.mecourse.com/landinig/ software/software.html) was used to measure 26 seed morphometric features (Table 2).

2.2.3. Linear Discriminant analysis

The morphometric parameters were used to build a database of features descriptive of seed size and shape. Statistical analyses were executed using the IBM SPSS software (Statistical Package for Social Science) release 16.0 (SPSS Inc. for Windows, Chicago, Illinois, USA).

The data were statistically processed by linear discriminant analysis (LDA) to identify and discriminate among the investigated apple varieties.

LDA is a method generally used to classify/identify unknown groups through the quantitative and qualitative variables (Sugiyama, 2007). Therefore, LDA is able to select and change the different predictor variables entered into the database minimizing the classification of short distance achieving and maximum the discrimination between the different classes (Hastie et al., 2002; Holden et al., 2011; Rencher et al., 2012; Kuhn and Johnson, 2013).

To verify the existence of some correlation between the seeds morphology and skin colour. The 25 apple varieties were characterized according to the descriptors of the International Union for the Protection of New Varieties of Plants (UPOV) (UPOV TG / 23/06, 2013) (Table 3) and those reported by the International Board for Plant Genetic Resources (IBPGR), (IBPGR 2015) (Table 4).

2.2.4. Multivariate statistical data analysis

From image analysis of apple varieties, an X matrix was created and subsequently was elaborated through chemometric techniques using SIMCA Software (14.0, Umetrics, Umeå, Sweden). In a multivariate analysis, data set has to be pre-treated and converted in a more eligible form to the analysis. In this work, the unit variance scaling was used. To show the complexity of a phenome constituted by a large number of variables using a small number of summary indicators (latent variables) principal component analysis was achieved (PCA). The PCA may be very useful to investigate variables measured on a large number of samples and to provide further support to understand the complex connection between the morphology of the seeds and characteristics of the fruit. In fact, multivariate data analysis techniques can be used to model factors and responses and understand the characteristics of different systems and process (Zude et al., 2003; Perk et al., 2010; Caboni et al., 2017; Murgia et al., 2016). This explorative method identifies the distribution of a data set and highlights similarities and differences no suspected among the data. PCA results are reported into different plots. The scores plot reported the samples projection into the model space, calculated by the use of principal components, while the loadings plot reports the projection of variables, using the same rules. These two plot can be reported overlaid as a Biplot. The quality of the model can be evaluated by the R^2 and Q^2 parameters. The R^2 is the fraction of the variation of the variables explained by the model. Q^2 is an estimate of the predictive ability of the model calculated by cross-validation. To better appreciate the presence of outliers Hotelling's T^2 and DmodX analyses were achieved. With the aim to classify the different classes of apples, a discriminant analysis (PLS-DA) was performed. The generated R^2Y and Q^2 values describe the reliability and the predictive ability of the fitting. Q^2 is made on the basis of a cross-validation analysis. R^2Y described the classificatory power of the model. Permutation test, a non-parametric test, was also performed to highlight the classificatory power of the model. A variable importance in the project test (VIP) gave the measure of a variables importance in the PLS-DA model.

2.2.5. Univariate statistical analysis.

GraphPad Prism software (version 7.01, GraphPad Software, Inc., CA, USA) was used to verify the significance of discriminant variables obtained by the supervised analysis. A one-way ANOVA test was performed and $P = 0.05$ was used as a limit of significance.

3. Results

3.1. Linear Discriminant Analysis

A first comparative analysis of the 25 apple varieties from Sardinia was performed, achieving 27% cross-validated grouped cases (SM 1; SM 2).

The highest discrimination was achieved by 'Appione' (70.8%), 'De Ferru' (60.4%) and 'Laconi B' (67.3%) (SM 1). For the same varieties, a second analysis was performed considering the apple group division according to the colour classifications UPOV 35, 37, 39 and IBPGR 6.2.12 and 6.12.13.

Considering the UPOV 35 parameter (ground colour), the 25 varieties were divided into six groups (Table 3a; SM 2). The LDA analysis conducted on these six groups achieved cross-validated grouped cases of 54.9% (Table 3a; SM 2). The highest classification was obtained for the yellow apple group (YG) with a 91.5% of classification (Table 3a, SM 2). Furthermore, considering the UPOV 37 parameter (over colour), the 25 varieties were divided into another six groups, the LDA achieving a cross-validated of 41.4% (Table 3b,). In this case, the highest classification was obtained for the red apple group (RR) with a correct percentage of classification of 84% (Table 3b). Finally, considering the UPOV 39 parameter (colour distribution), the 25 varieties were divided into six groups and in this case, the LDA achieving a cross-validated grouped cases of 36.9% (Table 3c). The group with uniform and the mottled colour (1) was classified with a high level of discrimination 81% (Table 3c).

Additional analyses were conducted considering the ground colour IBPGR 6.2.12 and IBPGR 6.12.13 colorimetric parameter (Table 1). Considering the IBPGR 6.2.12, the 25 varieties were divided into four groups, the LDA achieved cross-validated grouped cases of 66.8% (Table 4a; Fig. 2a). The green/yellow apple group (GY) obtained the highest percentage of discrimination with a 98.8% of classification (Table 4a). In this case, all other groups tend to be confused with the yellow/green apple group (Table 4a).

Finally, LDA conducted on five apple groups considering the parameter IBPGR 6.12.13 (over colour) were divided in to five groups and LDA achieved cross validated grouped cases of 59.9%. The high level of discrimination has been shown for the red apple group (RR) with a 94.4% (Table 4b; Fig. 2b). Moreover, the other groups tend to be confused with the group with the highest percentage of discrimination (Table 4b).

Considering that the highest classification percentages were obtained by the ground colour colorimetric parameters UPOV35 and IPBGR 6.2.12, we selected seven apples representative of all colorimetric parameters and performed the LDA and PCA considering only the UPOV35 and IPBGR 6.2.12 parameters (Table 1).

A first comparative analysis of seven varieties was performed by LDA, obtaining cross-validated grouped cases of 56.1% (Table 5a; Fig. 3a). Almost all varieties obtained a good percentage of discrimination except for the varieties 'Di Luglio' that tends to be confused with 'Appicadorza' (21,7%), 'Bianca di Ussassai' (16,7%) and 'De Ferru' (15%), respectively (Table 5a).

Considering the UPOV 35, the seven varieties were divided into four groups (Table 5b; Fig 3b), in this case the LDA showed, a cross-validated grouped cases 66.8%, were the green/white (GW) group was the best discriminated with a percentage of 81.5% (Table 5b). Moreover, LDA analysis showed that the yellow/green (YG) group was confused with the yellow (YY) apple group in 45% of the cases (Table 5b).

Finally, the LDA analysis performed on three groups of apples classified according to the IBPGR 6.2.12 parameter showed that almost all groups were correctly discriminated, with a cross-validated grouped cases of 69.9% (Table 5c; Fig 3c). In this case the yellow (YY) group was the best discriminated with a percentage of 83,7% (Table 5c).

3.2 Multivariate statistical data analysis

Based on the morphometric analysis of the seven selected apple varieties based on the ground colour UPOV35 and IPBGR 6.2.12 (Table 5a) a 437 X 26 matrix was shaped and analyzed by a multivariate data statistical analysis using the SIMCA software. The matrix was set up with 437 seed samples (Table 5a) and 26 morphometric parameters (Table 2). The Hotelling's T^2 and DmodX analysis showed 24 outliers that were excluded from the pool of samples. A new PCA was than performed showing the following validation parameters: $R^2X=0.93$ and $Q^2=0.88$. The results, reported as a Biplot in figure 4a, display different clusters along both of the two principal components. No clusters were observed based on the geographical location or varieties classification. Considering the ground skin colour (IBPGR 6.2.12), the White-Creamy (WC) samples clustered along the second principal component. This cauterization is due to the minR and the Breadth parameters. On the other hand, the yellow (YY) and yellow/green (YG) samples were more scattered indicating a strong infraclass variability (Fig. 4a).

Based on the UPOV 35 classification, the PCA showed different clusters among the first principal component. In fact, in the scores plot of figure 4b it is remarkable a clusterisation of class GY and BO classes on the left side of the plot, while the GW class clustered on the right side. On the other hand, the YY class appeared more scattered in both of the two first principal components.

Excluding the YY class from the model the resulted PLS-DA of the remained three classes BO *vs* GY *vs* GW showed an R^2Y of 0.51 and a Q^2 of 0.49 (Fig. 4c). Classificatory values are reported in table 6 from the classification test. From the loadings and the VIP analyses the resulted discriminant morphometric parameters were: Feeret, MaxR, MBCRadius, CHull, Perim, Pixels, Area, AspRatio and ArEquivD for the GW class, while Breadth, RFactor, Compactness, Roundness, MinR, Rectang Mod Ratio and Circ for the GY and BO classes (SM 3). All the variables were subjected to an ANOVA non parametric test to confirm the significance of the variance taking $P=0.05$ as the limit of significance.

Total	437	81,75%	142	255	40

4. Discussion

Considering the importance of the apple skin colour in breeding program, we have investigated this phenotypic characteristic by seed image analysis and using two different types of statistical analysis: LDA and PCA.

The first LDA analysis conducted on 25 apple varieties showed a high degree of discrimination for the varieties ‘Apione’, ‘De Ferru’ and ‘Laconi B’. These varieties come from the Laconi territory (placed in the Sarcidano region), that was considered for a long time one great biodiversity area of wild and cultivated plant species.

In fact, the literature reported that already in 1800 there have been more than 65 thousand fruit trees such as almonds, walnuts, chestnuts, figs, pears, apricots, cherries and plum trees (Agabbio et al., 1994; Angius, 2006). This testifies that in this area several fruit species have been cultivated for a long time and that probably many of them have been preserved to present day. In fact, ‘Apione’, ‘De Ferru’ and ‘Laconi B’ are considered the ancient local Sardinian varieties (Agabbio et al., 1994) and this could justify the high level of diversity when compared to the other apple varieties studies in this work.

In addition, the LDA analysis, considering the different UPOV and IBPGR classifications, allowed studying the relationship between the seed morphology and the apple skin colour.

LDA showed a high discrimination between the apple groups with yellow/green ground colour and red over colour. Even considering the other colorimetric groups it was observed that these tend to be confused with ground colour yellow/green and the red over colour.

Some considerations about this result can be attributed to the ability of some apples to develop the red skin colour. As it is well known, the colour of the fruit skin is due to anthocyanin pigments that produce colors ranging from red, blue and purple (Pomar et al., 2005; Torres et al., 2011; Jaakola, 2013). Red fruit skin colour is an important characteristic for consumer preference and marketability (Allan et al., 2008). Thus, several genetically studies have been conducted to understand which mechanisms involved in the red coloring of apples (Honda et

al., 2002; Kim et al., 2003; Ubi, 2004; Allan et al., 2008; Liu et al., 2013). These studies have established that the red coloration is induced by specific alleles (Zhang et al., 2014; Chagné et al., 2007, 2013; Ban et al., 2007; Lin-Wang et al., 2010). In addition, other studies have established that apples with yellow/green colour easily developed red colour respect to yellow apples after being properly stimulated (Honda et al., 2002; Liu et al., 2013). Thus, the correct classification of yellow/green and red apple groups by LDA could be related to the capacity of these apples to develop red coloring in their skin.

When the UPOV 39 colorimetric parameter was considered, the results obtained with the LDA showed a low discriminating power, in fact, all groups tend to be confused with the uniform and mottled colorimetric parameter.

The result obtained by comparing the seven varieties of apples through LDA shows how image analysis is able to discriminate the varieties studied considering them as individual varieties and as considering descriptive colorimetric parameters. In fact, the results achieved considering these small sample of apples and analysed by LDA and the multivariate statistical data analysis, suggest that the apple groups with ground colour green/white in the case of UPOV 35 and yellow for IBPGR 6.2.12 were the groups that obtained the best classification.

Considering the UPOV 35 colorimetric classification, the groups of apples that tend to confused among themselves were the group with ground colour yellow and yellow/green respectively. These results were confirmed with LDA and PCA analysis. The same result also occurred with IBPGR 6.2.12 classification. In this case, the yellow apple group were confused with the green/yellow group.

Moreover, based on the UPOV35 skin colour classification from the multivariate statistical analysis, several morphometric parameters were found statistically discriminant for the different colour classes. These results highlight a connection between the variability of seeds shape and the apple skin colour. Taking in consideration the good statistical results obtained from both analysis, the multivariate approach, used together with the morphometric analysis, can be used in future as original tool for the investigation of skin colour phenotype in apple varieties.

The most important result of this work is the demonstration that there is a direct correlation between seed morphology and apple skin colour. This relationship has never been described until now and it is an important starting point to investigate phenotype characters in modern varieties.

CHAPTER 2: Seed morphometry is suitable for apple germplasm diversity-analyses.

1. Introduction

The Rosaceae family comprises about 3,000 taxa that include many genera of great importance for human nutritional and ornamental use (Hancock, 2008). Among these, the genus *Malus* comprises about 55 species, including the domestic apple (*Malus domestica* Borkh.), one of the most economically important fruit crops grown in temperate zones (Zohary et al., 2012).

M. domestica Borkh. domestication likely began in the Tian Shan Mountains in Central Asia (Harris et al., 2002; Cornille et al., 2012). This area contains multiple crop wild relatives (CWR) of domestic apples, such as *M. sieversii* (Ledeb.) M. Roem., which is fully interfertile with *M. domestica* (Zohary et al., 2012). Other important species of wild apples have genetically contributed to domestic apple, including *M. orientalis* Uglitzk. ex Juz., with a distribution range identified in the Caucasus, and *M. sylvestris* (L.) Mill., distributed primarily in Europe (Cornille et al., 2014).

Molecular marker studies of wild and domesticated apples have confirmed the diffusion of apple across the silk road from Central Asia, passing through Turkey towards Europe (Cornille et al., 2013a, 2013b, 2012; Velasco et al., 2010; Harris et al., 2002). Nevertheless, the origin of apple domestication remains partially unclear because of interfertility and self-incompatibility of *Malus* species, which can hybridize, thereby generating highly variable progenies (Zohary et al., 2012; Cornille et al., 2012; Velasco et al., 2010). There are over 10,000 varieties of apples worldwide, showing huge variability in their traits, especially pomological features such as the fruit size, skin colour and taste (Cornille et al., 2014, 2012; Harris et al., 2002).

Today, the number of modern commercial varieties has been reduced because of clonal selection and breeding programs, which used a small number of genotypes (Hokanson et al., 2001; Noiton and Alspach, 1996). For this reason, to maintain the greatest variation of alleles that can be exploited in breeding programs, several researchers have recommended protecting and preserve CWRs and old apple varieties (Liang et al., 2015; Way et al., 1990; Nnadozie et al., 2003).

Several genetic studies were conducted to investigate the origins of apple domestication and genetic diversity within the species or within the local germplasm (Urrestarazu et al., 2016, 2012; Cornille et al., 2012; Liang et al., 2015; Velasco et al., 2010).

Liang et al. (2015), by simple sequence repeats (SSRs) analysis, described the genetic diversity within a large number of apple varieties (belonging mainly to the Italian peninsula), with the

goal of identifying synonymy and homonymy (which are extremely difficult to detect through phenotypic traits) and exploring the genetic structure detectable in this large asset of accessions. Other authors, by seed image analysis techniques and the linear discriminant analysis (LDA), have investigated the diversity in cultivated species such as *Vitis vinifera* L. spp. *vinifera*, *Olea europaea* L., *Cucumis melo* L. and *Prunus domestica* L., (Orrù et al., 2015, 2013, 2012; Ucchesu et al., 2017, 2016, 2015; Sabato et al., 2015; Piras et al., 2016; Sarigu et al., 2017).

The main objectives of this work were to:

(1) build a database of seed morphological variables of apple cultivars, suitable for variety characterization;

(2) assess the phenotypic diversity of apples by morphological seed image analysis techniques and by LDA;

(3) compare our seed image analysis data with a genetic study previously conducted on the same varieties (Liang et al., 2015).

2. Materials and Methods

2.1. Apple germplasm varieties

In this work, we have investigated 42 apple varieties previously subjected to genetic analysis by Liang et al. (2015) (Table 1).

The fruits were harvested in the apple collection field of the Cadriano Experimental Station of the Department of Agricultural Sciences (University of Bologna) at full ripening. After removing the flesh, seeds were cleaned, washed and naturally air-dried in the laboratory of the Sardinian Germplasm Bank (BG-SAR), University of Cagliari.

To ensure the highest morphological variability among seeds and to compare morphometric results with genetic data, 10 fruits of each cultivar were harvested from the same tree previously used for the genetic analysis. To facilitate the presentation of results and sample grouping, each cultivar has been coded (Table 1).

2.2 Seeds image analysis

Digital image analysis is an innovative method of recent use that allows a high number of morphometric features of the seeds (Keefe and Draper, 1988).

This method gives several advantages such as low-cost analysis, non-destruction of the sample, analytical speed compared to conventional methods, even in the presence of a large amount of data and the ability to standardize the process making it interactive and easy to use (Chitra et al., 2016; Sandeep et al., 2013; Nikam and Kakatkar, 2013).

Moreover, this methodology can be applied to a large field of investigations such as the agronomic one, for example for identifying new cultivars or identifying possible synonyms and homonyms groups (Orrù et al., 2015, 2013, 2012; Ucchesu et al., 2017, 2016, 2015; Sabato et al., 2015; Piras et al., 2016; Sarigu et al., 2017).

The digital images of all seeds were acquired using a flatbed scanner (Epson Perfection V550), with a digital resolution of 800 dpi for a scanning area not exceeding 1024 × 1024 pixels (Bacchetta et al., 2008). The images were processed and analysed using the open source software ImageJ v. 1.49. The Particles8 plugin (Landini, 2006) was used to measure 26 seed morphometric variables (Table 2, Fig. 1).

To increase the number of discriminant parameters, 80 elliptic Fourier descriptors (EFDs) of the seed's contour shape were computed using the open source SHAPE software (Iwata and Ukai, 2002). This method reports the boundary of the seed projection as an array of complex numbers, which correspond to the pixel positions on the edge of the seed. Therefore, from the seed apex, defined as the starting point in a Cartesian system, chain codes are generated (Kuhl and Giardina, 1982). In total, 26 morphometric variables were measured.

2.3. Statistical analysis

Morphometric data were processed and statistically analysed by applying a stepwise LDA method using IBM SPSS (Statistical Package for Social Science, release 16.0). The LDA method is commonly used to classify or identify unknown groups characterized by quantitative and qualitative variables (Sugiyama, 2007), finding the combination of predictor variables with the aim of simultaneously minimizing the within-class distance and maximizing the between-class distance, thus achieving maximum class discrimination (Hastie et al., 2002; Holden et al., 2011; Rencher and Christensen, 2012; Kuhn and Johnson, 2013).

This method allowed us to reduce the dataset size without losing important information and to classify statistical cases into groups (Fukunaga, 2013; Duda et al., 2012; Hastie et al., 2002; Holden et al., 2011; Sugiyama, 2007). Using three statistical variables (Tolerance, *F*-to-enter and *F*-to-remove), the stepwise method identifies and selects the most statistically significant variables among the 26 measured on each seed. The tolerance value, *F*-to-enter and *F*-to-remove values define the power of each variable and their role in the model. At each step, the variable with the largest *F*-to-enter value that exceeds the entry criterion chosen ($F \geq 3.84$) was added to the model. All variables with a value below 3.84 were excluded from the analysis (Venora et al., 2009). Finally, a cross-validation procedure was applied to verify the performance of the identification system, testing individual unknown cases and classifying them based on all others. This procedure, also referred to as rotation estimation (Picard and Cook, 1984; Kohavi, 1995), was used to evaluate the performance and to validate any

implemented classifier. Here we applied the leave one out cross validation (LOOCV) procedure (SPSS 2006).

Fig. 1. Variety *M. domestica* utilised in this study.

Table 2. List of the 26 morphometric seed features measured on endocarps and calculated by Particles8 plugins from ImageJ v. 1.49.

Parameter	Description
Perim	Perimeter, calculated from the centres of the boundary pixels
Area	Area inside the polygon defined by the perimeter
Pixels	Number of pixels forming the seed image
MinR	Radius of the inscribed circle centred at the middle of mass
MaxR	Radius of the enclosing circle centred at the middle of mass
Feret	Larges taxis length
Breadth	Largest axis perpendicular to the Feret
CHull	Convex hull or convex polygon calculated from pixel centres
CArea	Area of the convex hull polygon
MBCRadius	Radius of the minimal bounding circle
AspRatio	Aspect ratio = Feret/Breadth
Circ	Circularity = $4 \cdot \pi \cdot \text{Area}/\text{Perimeter}^2$
Roundness	Roundness = $4 \cdot \text{Area}/(\pi \cdot \text{Feret}^2)$
ArEquivD	Area equivalent diameter = $\sqrt{((4/\pi) \cdot \text{Area})}$
PerEquivD	Perimeter equivalent diameter = Area/π
EquivEllAr	Equivalent ellipse area = $(\pi \cdot \text{Feret} \cdot \text{Breadth})/4$
Compactness	Compactness = $\sqrt{((4/\pi) \cdot \text{Area})}/\text{Feret}$
Solidity	Solidity = Area/Convex_Area
Concavity	Concavity = Convex_Area-Area
Convexity	Convexity = Convex_hull/Perimeter
Shape	Shape = $\text{Perimeter}^2/\text{Area}$
RFactor	RFactor = Convex_Hull /$(\text{Feret} \cdot \pi)$
ModRatio	Modification ratio = $(2 \cdot \text{MinR})/\text{Feret}$
Sphericity	Sphericity = MinR/MaxR
ArBBox	Area of the bounding box along the feret diameter = Feret·Breadth
Rectang	Rectangularity = Area/ArBBox

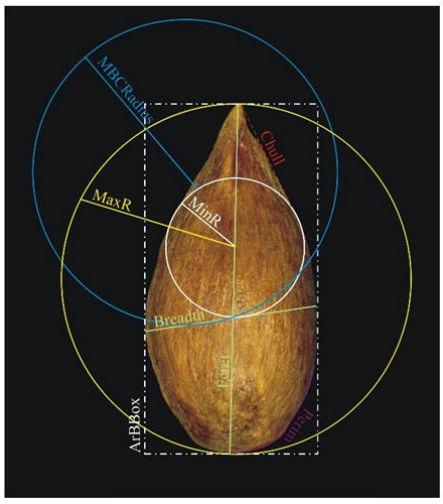

Fig. 2. Graphical representation of principal morphometric variables measured on each apple seed (refer to Table 2).

3. Results

A first comparison among the 42 apple varieties was executed, achieving a 38.8% cross-validation for correct identifications. This first analysis showed a high classification for some varieties, including ‘Bella del Giardino’ (70%), ‘Amasya’ (60.1%), ‘Paradisa’ (59.4%) and ‘Durello di Forlì’ (54.6%) (Table 3).

Seeds from the variety ‘Eppia’ showed the lowest discriminant characteristics, with a value of only 14% (Table 3), showing a degree of similarity with the ‘Francesca’ variety of 19.2%. Other varieties that showed a low level of discrimination were ‘Red Chief’ (16.2%) and ‘Cavicchio di Levizzano’ (18%) (Table 3).

By LDA analysis, the 42 apple varieties could be subdivided into two large groups labelled ‘A’ and ‘B’ (Fig. 3). The comparison between these two groups showed a classification of 100% and 91.6%, respectively (Table 4). No subgroups were identified in group ‘A’ and ‘B’. Convexity, solidity and concavity were identified as the most discriminant variables (Table 5).

With the aim of identifying possible similarities, we compared groups ‘A’ and ‘B’ with the groups ‘G1’ and ‘G2’ reported by Liang et al. (2015) (Table 3). In a preliminary analysis, the ‘G1’ and ‘G2’ groups were individually included in the database as unknown groups and compared by LDA with group ‘A’ and ‘B’. In the LDA analysis in which the ‘G1’ group was inserted as an unknown, we detected a correlation with groups ‘A’ (69.63%) and ‘B’ (30.36%) (Table 6). In addition, the same analysis was conducted by inserting group ‘G2’ as an unknown. In this case, the LDA showed a correlation with group ‘A’ of 85.26% and with group ‘B’ of 14.73% (Table 6).

Moreover, a comparison between the groups reported by Liang et al. (2015) using LDA analysis discriminated the two groups with a percentage of 27.6% for ‘G1’ and 91.8% for ‘G2’ (Table 7). A further analysis was conducted to verify the existence of subgroups within the ‘G1’ and ‘G2’ groups, as had been identified by Liang et al. (2015). As a result of this analysis, subgroups ‘C’ and ‘D’ were identified within group 'G1’ (Fig. 3), and subgroups ‘E’ and ‘F’ within the group ‘G2’ (Fig. 4).

In agreement with the genetic analysis (Liang et al., 2015), that included ‘Eppia’ and ‘Francesca’ varieties in ‘G2’ (‘G2.U’ subgroup), the LDA method also classified these two varieties within ‘G2’ (Table 8). However, the ‘Paradisa’ variety, which was assigned to ‘G1’ by the genetic analysis (‘G1.U’ subgroup), was assigned to ‘G2’ by the LDA method (Table 8).

Table 3. Apple varieties grouping and discriminant percentages determined by LDA using either our seed image data or the genetic data of Liang et al. (2015).

4. Discussion

In this work, we report the findings of an LDA based on seed morphometric parameters from 42 apple varieties. Our aim was to investigate the phenotypic diversity among these varieties and to compare this data with available genetic data (Liang et al., 2015). The first comparative analysis identified some varieties with high percentages of discrimination (e.g. 'Bella del Giardino'), as well as others with low separation (e.g., 'Eppia'). This high variability between *Malus* varieties can be explained by the origin of its genotypes; in fact, the currently cultivated varieties of apples are the result of a complex and long genetic history, in which natural evolution and human selection, presumably since prehistoric times, have contributed to shaping the extant species (Angelini, 2009; Cornille et al., 2012).

The variable degree of seed discrimination might be explained by the fact that apple fruit and seed development are strictly related to a complex network of endogenous and exogenous factors (Eccher et al., 2014), such as hormones (Gillaspy et al., 1993) and gene expression regulation by MADS-box genes (Sung et al., 2000; Yao et al., 2001). This developmental cross-talk involves a large number of genes and biosynthetic pathways, whose effects on the respective phenotypes are largely unknown (Eccher et al., 2014).

The phenotypic diversity among the tested seeds is presumably the result of the activation or repression of a large number of genes (and related allelic variants), with potential contributions from environmental factors.

In addition, in this case, the LDA analysis proved to be a valid method for discriminating groups and subgroups, as previously demonstrated by the genetic analysis conducted by Liang et al. (2015).

The comparison between the 'A' and 'B' groups show a clear differentiation, with a higher classification for group 'B'. This might be because group 'B' is composed of a greater number of varieties sharing common phenotypic traits.

By LDA, the 'Gelata', 'Verginella', 'Limoncella' and 'Limoncella Uriddu' varieties have been classified into the same group ('A'), confirming the results obtained by SSR analysis in which these varieties presented the same electrophoretic pattern (Liang et al., 2015). These results, therefore, suggest that the morphological and molecular approaches produce similar findings.

Moreover, by comparing the principal groups 'G1' and 'G2' by LDA, we detected a low classification for group 'G1', which tends to be confused with 'G2'. This is probably because 'G2' is larger than 'G1' and is composed mainly of varieties classified with a high percentage. In addition, as evidenced by genetic analysis, the 'G2' group is composed mostly of Italian varieties, whereas the international standard varieties are assigned to 'G1'.

Both approaches evidenced the existence of two principal groups, which, in turn, are divided into two additional sub-groups. The composition of the sub-groups, identified through the LDA approach, suggests a partial correlation of varieties with those identified by genetic analysis. Finally, the comparison of the "Francesca", "Eppia" and "Paradisa" varieties, which were assigned by genetic analysis as ‘G1.U’ and ‘G2.U’, have obtained a total allocation in the ‘G2’ group. This is because these three varieties belong to group ‘A’, which is mostly composed of varieties included in the ‘G2’ group.

These differences can be partly explained by the fact that the molecular markers (SSRs) used by Liang et al. (2015) identified a large number of polymorphisms in specific loci, whereas the morphometric analysis highlights a phenotypic variability that cannot be directly compared with those detected by the SSR analysis (Orrù et al., 2012). In fact, genes that are responsible for this variability are located in genomic positions that are not necessarily covered by the analysed SSRs. These observations could be used to understand the relationships between the morphological results and the molecular analyses reported by Liang et al. (2015). The different basis of the discrimination in groups made by genetic and morphological approaches could explain the few discrepancies observed in the present study.

Liang et al. (2015) identified the existence of the two groups, although these were little differentiated. The additional division into subgroups was determined by a nested approach, as described by Urrestarazu et al. (2012). Another recent paper that analysed the genetic diversity at the European level identified the existence of three main groups: varieties coming from the North East of Europe, those from the Western countries and mainly Mediterranean varieties collected in Italy and Spain (Urrestarazu et al., 2016). In addition, in this case, the three groups were linked with the geographical regions of origin, even if they were little differentiated. This would reflect a situation whereby the varieties from a given region were more frequently derived from crosses between parental varieties from the same region, rather than from varieties found elsewhere. Most of the samples analysed in this study belong to the Mediterranean group, and would, therefore, be expected to group together if compared to cultivars of a different origin; however, the number of non-Mediterranean genotypes included in our study was probably insufficient to allow the detection of an external group based on morphologic traits. Moreover, the migration of plant material associated with human movement, together with hundreds of years of empirical selection, have likely caused a significant gene flow across Europe (Urrestarazu et al., 2016), making it difficult to identify well-defined phenotypical differences between the main groups and subgroups of extant varieties.

5. Conclusion

In this work, the use of digital seed image analysis applied to investigate phenotypic characteristics of the apple samples has allowed to obtain valuable information that can be compared with genetic analysis.

Overall, this work has allowed the creation of a morphometric seeds database of Italian apple varieties, suitable for the characterization and conservation of germplasm. Moreover, a global correlation has been shown especially in the subdivision of two main groups and respective subgroups by both phenotypic and genotypic approaches. Furthermore, we provided evidence that seed morphometric and genetic analyses support the characterization of biodiversity among varieties of fruit tree species. These findings will be useful for efforts to preserve the genetic diversity of cultivated plant species and to enlarge the genetic component of existing fruit breeding programs.

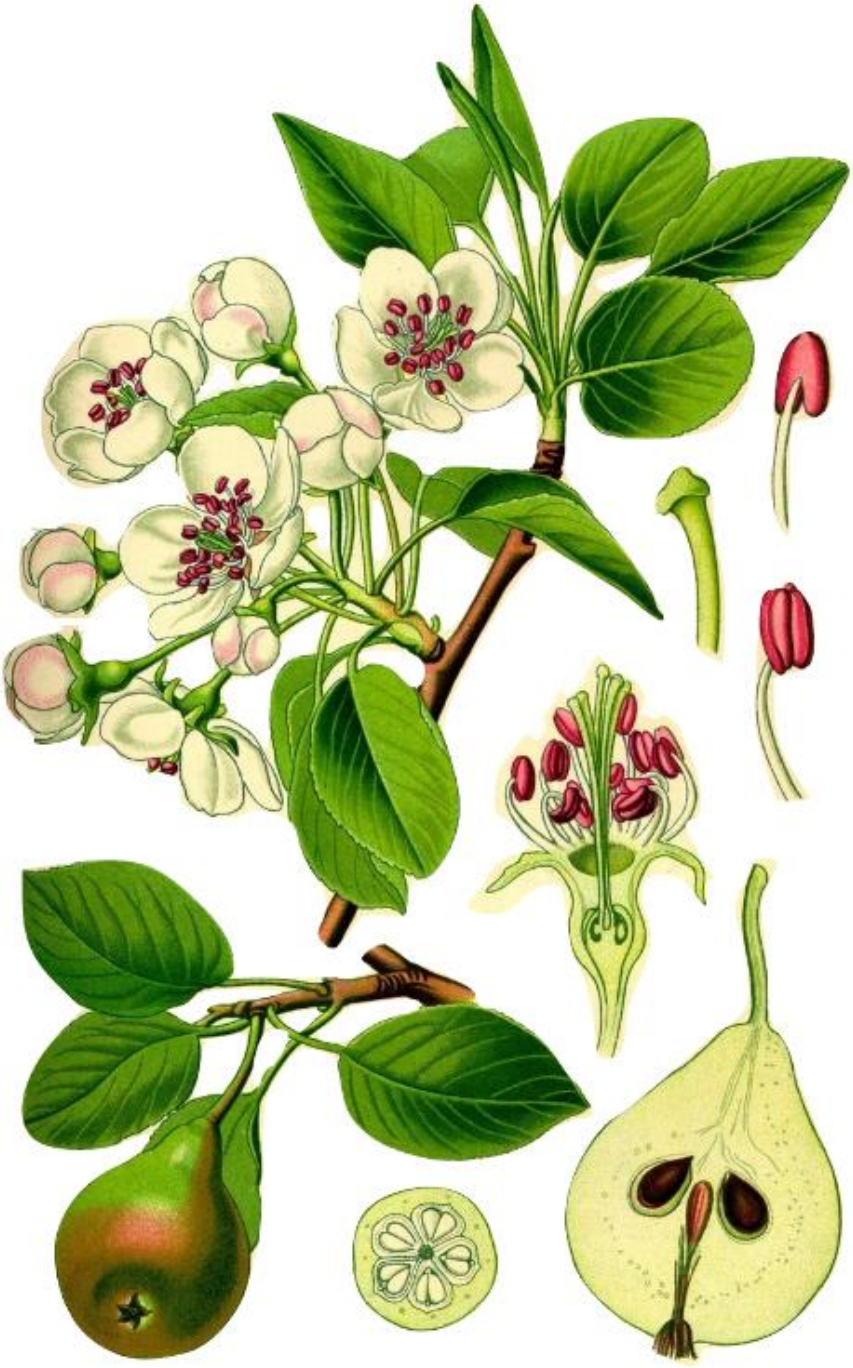
The species *Pyrus communis* L.:



1. Botanical description

The *Pyrus* genus belongs to the family of the Rosaceae subfamily Pomidae.

The flower, gathered in a bunch of corymbiform of 5-15 flowers, is hermaphrodite with about 20 stamens, 5 petals of generally white color, sometimes rosé; The chalice is persistent in Western species, while it is generally fallen in the eastern species; The peduncle, which is generally elongated and curved, may be more or less fleshy in western species, not fleshy in the eastern ones.

The *Pyrus* genus is characterized by widespread autoincompatibility and factorial incompatibility. The fruit is a boss, also called a fake fruit because the part of the building is made up of the flower recipe. The pulp is predominantly white-cream, but it can also be of red colour more or less clear.

The simple leaves have varying shapes and sizes, are alternate with 2/5, fillets, crunchy, with crinkled edges in Eurasian species, clenched at a sharp angle or crenated silk in the oriental species, sometimes wavy. The tree, depending on the species, is a thorny bush, or as in cultivated varieties, a tall stem, pyramidal (up to 20 m and upwards), (Pignatti, 1982).

2. Origin

Pear belongs to rosaceous family, being a close "cousin" of the apple, but with some particularities that make this fruit special with a delicate flavour (Silva et al., 2014).

Common pears are thought to have developed from plants growing natively in Europe and Northern Asia. They were popular among the ancient Greeks and Romans, although they were used in drinks and cooked dishes rather than eaten raw, since the ancient varieties of pear were less palatable raw. However, through breeding, pears were made safe to eat raw and became a popular dessert fruit. They were brought to America in 1797, and continue to be popular worldwide today (Ferreira et al., 2002).

Most botanists believe that the *Pyrus* genus has differentiated in the Tertiary period, in the mountainous territory of present-day western China; from there it would have been dispersed both east and west, adapting to the different conditions of climate and territory, differentiating the species currently known (Fideghelli, 2007).

There are two domestication centers and primary origin of the genus *Pyrus*: the first is located in China, the second located in Asia Minor to the Middle East, in the Caucasus mountains, and a third secondary centre located in Central Asia (Zukovski, 1962).

Vavilov has identified two centers of primary origin:

A) China, where the species *P. pyrifolia*, *P. ussuriensis* and *P. calleryana* are grown;

B) Middle East (Caucasus, Asia Minor), the center of primary origin of the *P. communis*.

A third secondary centre (C) was also reported in Central Asia (northwestern India, Afghanistan, Tajikistan, Uzbekistan and the Tianshan province of China) (Vavilov, 1992), where *P.communis* is present hybridized with *P.* x *bretschneideri*.

In its evolution, *P. communis* hybridized with several species in Asia Minor and Europe:

P. elaeagrifolia, P. salicifolia, P. syriaca, P. nivalis, P. caucasia.

Of the species *P. communis* there is the pyramidal botanic form or variety present also in Southern Mediterranean Italy, which Linneo considered the wild form from which the cultivated varieties would have evolved.

In addition, cultivated varieties of the Eastern Peruvian are probably derived from natural hybridization among the various species, in particular, *P. pyrifolia*, *P. ussuriensis* and *P. betulaefolia*. *Pyrus* x bretschneideri is, among the various natural hybrids, the most important one from the point of view of cultivated varieties.

All *Pyrus* species have a 2n = 34 chromosomal number and only a few *P. communis* cultivars are known to be polyploidy (Angelini, 2007).

3. Economic importance

Pear is an important ingredient in many cuisines and is thus an important economic crop (Jackson et al. 2003).

Three-quarters of all cultivated pears are grown in Asia, and the world's largest producer is China (Layne et al., 1975); it produced a massive 18 million tons in 2014 (FAOSAT). The United States and Italy are also large producers of the fruit. There are three economically important species, *P. communis* (European pear), *P. pyrifolia*, (Japanese pear or Nashi), and *P. usuriensis* (Chinese pear). Japanese and Korean cultivars are complex hybrids of *P. pyrifolia* and *P. ussuriensis*. Pear has similar uses to apple, although its popularity may be somewhat lower because the best quality is ephemeral in European pear. In European winter pears this eating quality is achieved by ripening after harvest. Pear cider is usually made from cultivars of *P. nivalis* and is called perry. The pear tree is also an important ornamental and is beloved in Asia where pear is considered a sign of good luck. In the United States, the most popular ornamental pear trees were selections of *Pyrus calleryana,* the Callery pear. These street trees can be found from Oregon to Ohio to New York, and south to Alabama and Georgia. *Pyrus koehnii*, an evergreen species native to Taiwan, is planted in California and Florida.

Pears are consumed more for their taste than for nutritional value and their medicinal benefits. It has a high nutritional value with reasonable amounts of vitamins A, B1, B2, B3 and C and minerals such as sodium, potassium, phosphorus, calcium, magnesium and iron (Gonsalves et al., 2002; USDA 2012). Research has shown, however, that they have been helpful in lowering

cholesterol, decreasing blood lipid levels and improving the health of the stomach and intestine by protecting the ulcers and improving the production of useful bacteria to our body.

In addition, pears have been useful in diets of people suffering from obesity, kidney dysfunction, hypertension and cystitis, stimulating the elimination of urine and the proper functioning of the kidneys (Ferreira, 2002).

The species *Pyrus spinosa* Forssk. :

1. Botanical description

It is a shrub or small tree with slow growth, which can add 4-6 meters with stems and main branches erect, light drizzle. The trunk has a bark of grey colour, frozen in ripe specimens. It has erect-patented branches with lentils almost null. Younger jets are often spineless, with a reddish bark often dense or covered with a dense, non-persistent dense characteristic. These young branches carry oval-shaped gems, dull, enclosed in 6-9 brunet bristles, hairy or glabrous eyelashes.

The leaves are very variable, generally oblong-lanceolate, (1-2,5 - 3-7 cm), with rounded or acute apex and rounded base. The bottom page is white-torment in the juvenile phase and almost disperses later. The upper part of the adult leaves is shiny and has bluish shades.

The petiole is 10-20 mm long and the margins are wholly or finely pruned.

The flowers (8-12) are collected in umbrellatory peaks. Petals, white and elliptical (5-6 - 7-8 mm), are wholly or more often slightly apical, with short nails at the base.

The buds on the end have a reddish colour similar to the apple tree. Flowering takes place from March to May depending on altitudes and exposure. Fruits, spherical piridion, 2-4 cm in diameter, with a sturdy peduncle and as long as the fruit or more. The colour varies from green to brown to yellowish dirt due to its presence on almost all of its superficial formations (freckles), which often come together to cover the whole fruit. The pulp is woody for the presence of chlorides and harsh. The fruits remain on the trees until the beginning of the winter season (Zancheri, 1976; Pignatti, 1982;).

The fruits, though rough and hardly harvested, can be consumed with the aid of a plummeting, ancient practice by which maturation is induced by depositing the fruit in straw beds.

Small pears harvested at the end of summer or autumn can be stored for long periods of time.

2. Habitat

P.spinosa is a Steno-Mediterranean species spread from Spain to Turkey with particular reference to the following regions: Catalonia, Provence, Central and Southern Italy, Istria, Dalmatia, South Serbia, Peloponnese, Crete, Rhodes, Bitinia and Thrace (Zohary, 1997; Giardina et al., 2007).

Within the limits of its area and the highest altitude of survival, *P. spinosa* proves to possess a great ability to adapt to almost every type of soil: It can then be encountered in heavily drained back-soil, in rocky semi-arid areas, or on limestone or basal soil rich in metal oxides. It may occasionally grow along the slopes of seasonal waterways or on areas regularly occupied by temporary pools. It is common along the margins of roads, wooded areas or discontinuous cultivated land.

3. Systematic description

The complexity of the *Pyus* genus is such that to date one or more homogeneous classification criteria cannot be indicated. Nevertheless, while awaiting the identification of a classification system that includes exhaustively all known species of the *Pyrus* genus, the method adopted and proposed by Koehne (1980) remains the only one recognized as valid by most such specialists. According to this method, *P. spinosa* Forssk. It is located within the *Pyrus* group that exhibits fruit with persistent residual goblet; this group also belongs to *P. communis* L.

P. spinosa is species among the most polymorphic and phenotypically variable. This variability is the source of a particularly large number of descriptions by various authors between the 19th and 20th centuries of new species with related combinations of names, many of which are now invalidated or reduced to the synonym or variety. *P.spinosa* is currently considered a Crop Wild Relative (CWR) of the *P.communis* species, presenting a primary gene pool that allows hybridizing easily with it, (Vincent et al., 2013).

CHAPTER 3: Seed image analysis to characterise Sardinian *P. communis* and *P. spinosa* and comparison with international varieties.

1. Introduction

Pear (*Pyrus communis* L.) after apple (*Malus domestica* Borkh.) and grape (*Vitis vinifera* ssp. vinifera) are one of the most important fruit trees cultivated in all temperate regions of the world (Wolko et al., 2010). Worldwide are produced 25,798,644 tons of pears where, Asia is the largest producer with 20,071,402 tones, followed by Europe with 2,976,540 tones, America with 1,869,017 tones, Africa with 758,522 tones and Oceania with 123,163 tones (FAOSAT 2014).

In Italy, the cultivation of the pear tree is strongly concentrated in Emilia-Romagna mainly in the triangle between Ferrara, Modena and Bologna, where in 2015 the production was 515,000 tons overall. In addition, Veneto and Sicily also boast considerable pear production (http://www.freshplaza.it/article/79363/Produzione-2015-di-pere-in-Italia-e-prime-indicazioni-commerciali).

Fossil evidence has shown that the genus *Pyrus* has differentiated in the Tertiary period (65 to 55 million years ago) and its origin has been placed in the mountainous areas of western and sub-western China (Kumar et al., 2017). Afterward, it would have expanded to adapt to the different climatic and environmental conditions, thus giving origin to present species (Rubtzov, 1944; Zielinski and Thompson, 1967). This location was also suggested by Nicolai Vavilov that in the 1930s identified two primary centres of domestication originated in regions extending from Asia west to the Caucasus (Vavilov, 1951). A third centre was also reported in Central Asia (northwestern India, Afghanistan, Tajikistan, Uzbekistan and the Tianshan province of China) (Zukovskij, 1962; Vavilov, 1992).

Domesticated cultivars of *P. communis* spp. *communis* hybridized with ancestors of *P. communis* subspecies and *P. nivalis* Jacquin. Also *P. communis* spp. *pyraster* and *P. communis* spp. *caucasian* are probably the ancestors of the cultivated European pear (Challice and Westwood, 1973).

Regarding pear tree cultivation, many species may have escaped the control of farmers, generating wild population that hybridizing with cultivars could have originated new pears variety (Dosdek, 1991; Aldasoro et al., 1996; Paganova, 2003).

The *P. communis* is practically the only one cultivated species in Europe, Africa, America, Oceania and West Asia, with few exceptions of local oriental productions. Wild populations are found in Europe, North Africa, West, Central and Eastern Asia and Japan (Terpò, 1992).

Cultivated pears were also known by the Greeks and Romans from about 2500 years ago (Hedrick, 1924).

During the Roman period, many pear varieties were introduced in Sardinia and some of these were mentioned by Elder Pliny in the "Naturalis Historia", at present day some of these still appear in the Sardinia germplasm (Agabbio et al., 1986). Moreover, during the Judicial period between the ninth and fifteenth centuries, pear had a great spread throughout Sardinia by grafting on the wild species (*P. spinosa* Forssk.), so called "pirastru" are widespread throughout the island, this maybe a sign of their ancient origin (Camarda and Valsecchi, 1983). Subsequently, in the Aragonese period (1323-1326 AD), the cultivation of pomaceae was intensely practised to support family needs. (Agabbio et al., 1994).

At present day, the local Sardinian varieties are progressively replaced with more productive modern ones, leading to the disappearance of local cultivars. Many of these ancient varieties are preserved from the CNR-ISPA catalogue fields (Nuraxinieddu, Oristano, Sardinia). The harvesting time of these varieties starts in June and ends late in November. Some of the late harvested varieties can only be consumed after a long storage period needed to ripen fruit and decrease its astringency. A characteristic core browning, known as 'ammezzimento' occurs in several ancient varieties and in the early harvested ones it takes place before or quickly after harvest while, it is a slow process in late-season harvested fruit. Moreover, this characteristic allows the autumn harvested pears to be preserved for a long time and consumed them throughout the New Year.

The loss of local varieties typical of a territory represents not only a serious biological, ecological and cultural defeat for the community but also the loss of great opportunities for development. Furthermore, for these local varieties, no morphological or genetic studies have been carried out for their preservation.

In order to counteract the phenomenon of genetic erosion of the old pear varieties in Sardinia, this work has been carried out to preserve germplasm diversity, and characterize pear varieties. The main objectives of this study are to investigate by seed image analysis the phenotype diversity of pears, in particular:

(1) the relationship between local cultivars and wild populations of Sardinian pear and national and international varieties;

(2) the phenomenon of pear over-ripening in Sardinian local cultivars.

2. Materials and Methods

2.1. Plant material

In this work, we have studied 65 *P. communis* Sardinian varieties from the CNR-ISPA catalogue field (Nuraxinieddu, Oristano, Sardinia) and seven varieties of *P. spinosa* collected in Sardinia (Table 1; Fig. 1). Moreover, additional 44 national and international varieties of *P. communis* were collected in the field catalogue of the experimental station of Cadriano of the Department of Agricultural Sciences Bologna, (Italy), and added in this study (Table 1; Fig. 2).

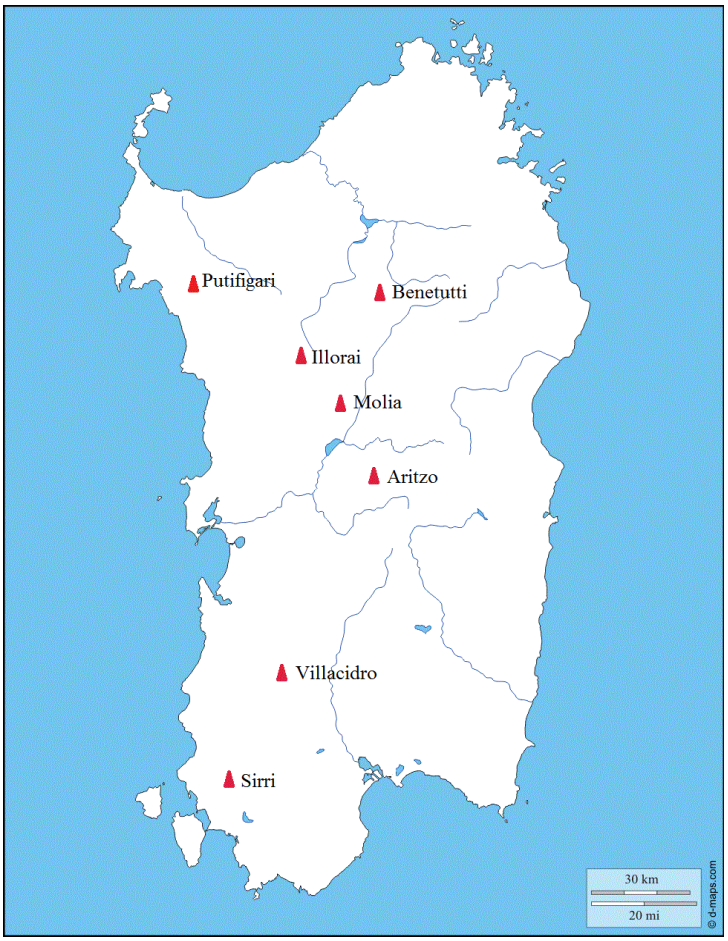

Fig.1 Distribution of *P. spinosa*, samples selected for this study.

Table 1. *P. communis* and *P. spinosa* seeds analysed in this study.
SA *P.c* = *P. communis* varieties of Sardinia; BO *P.c* = *P. communis* national and international varieties of Bologna; SA *P.s* = *P.spinosa* collected in Sardinia.

Fig. 2 *Pyrus* varieties provided by the Department of Agricultural Sciences Bologna used in this study.

The fruits were harvested at full maturity after removed the pulp, the seeds were cleaned, washed, and subsequently air dried according to the standard protocol adopted in the Germplasm Bank of Sardinia BG-SAR (Atzeri et al., 2012) (Fig.3).

Fig. 3 The protocol of the Germplasm Bank of Sardinia adopted to collect, clean and store pear seeds. (from upper left to right: seed removal, soaking and air-drying. Lower sequence from left to right: seed selection, packaging and storage).

2.2. Seeds image analysis

A total of 8,119 seeds were analysed using the seed image and Linear Discriminant Analysis (LDA) method.

Digital images of seeds were acquired using a flatbed scanner (Epson Perfection V550), with a digital resolution of 800 dpi for a scanning area not exceeding 1024×1024 pixels (Bacchetta et al., 2008) (Fig. 4). The images were processed and analysed using the open source software ImageJ v. 1.49 (http://rsb.info.nih.gov/ij). A plugin, Particles8 (Landini 2006), freely available on the official website (http://www.mecourse.com/landinig/software/software.html) was used to measure 26 seed morphometric features (Table 2; Fig.5).

The morphometric parameters were used to build a database of features descriptive of seed size and shape.

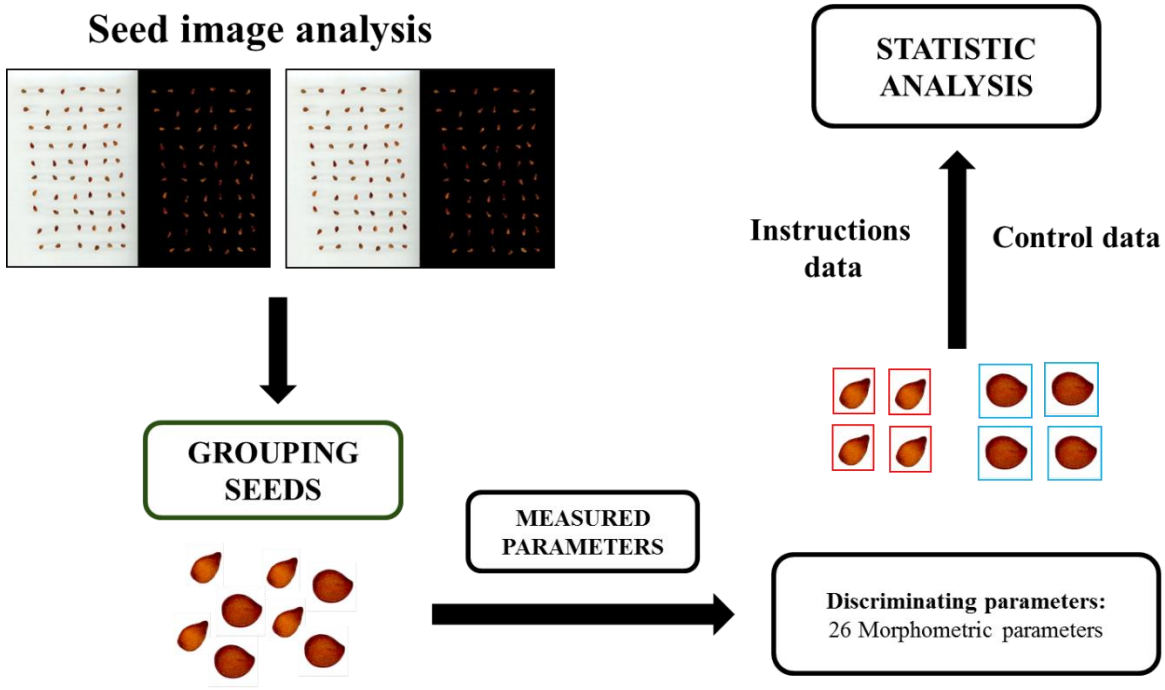

Fig. 4 Flow-chart of the seed image analysis.

2.3. Statistical analysis

Morphometric data have been processed and statistically analysed by applying the stepwise LDA method and by using the IBM SPSS software (Statistical Package for Social Science) release 16.0 (SPSS Inc. for Windows, Chicago, Illinois, USA). LDA method is commonly used to classify or identify unknown groups characterized by quantitative and qualitative variables (Sugiyama, 2007), finding the combination of predictor variables with the aim of minimizing the within-class distance and maximizing the between-class distance simultaneously, thus achieving maximum class discrimination (Hastie et al., 2001; Holden et al., 2011; Kuhn and Johnson, 2013).

This method allows reducing the dataset size without losing important information and classifying statistical cases into groups (Fukunaga, 2013; Duda et al., 2012; Hastie et al., 2001; Holden et al., 2011; Sugiyama, 2007). LDA achieve the highest-class discrimination combining the all predictor variables by minimizing the distance within the class (Holden et al., 2011; Rencher and Christensen 2012; Kuhn and Johnson, 2013). The stepwise method identifies and selects the most statistically significant features, among the 26 measured on each seed, using three statistical variables: Tolerance, *F*-to-enter and *F*-to-remove. The variable variance indicates by the tolerance value, *F*-to-enter and *F*-to-remove values define the power of each variable in the model and are useful in describing what happens if a variable is inserted and removed, from the current model. At each step, the largest F-to-enter value respect to the chosen value ($F \geq 3.84$) is added to the model. Therefore, all variables with values smaller than 3.84

will not be added to the analysis at the last step (Venora et al., 2009). Finally, a cross-validation procedure is applied to verify the performance of the identification system, testing individual unknown cases and classifying them according to all others. This procedure also called rotation estimation (Picard and Cook, 1984; Kohavi, 1995) was applied, both to evaluate the performance and to validate any implemented classifier. The validation procedure used here is the leave-one-out cross-validation (LOOCV) (SPSS 2006).

Table 2. Morphometric features measured on seeds and calculated by Particles8 plugins from ImageJ v. 1.49.

Parameter	Description
Perim	Perimeter, calculated from the centres of the boundary pixels
Area	Area inside the polygon defined by the perimeter
Pixels	Number of pixels forming the seed image
MinR	Radius of the inscribed circle centred at the middle of mass
MaxR	Radius of the enclosing circle centred at the middle of mass
Feret	Larges taxis length
Breadth	Largest axis perpendicular to the Feret
CHull	Convex hull or convex polygon calculated from pixel centres
CArea	Area of the convex hull polygon
MBCRadius	Radius of the minimal bounding circle
AspRatio	Aspect ratio = Feret/Breadth
Circ	Circularity = $4 \cdot \pi \cdot \text{Area}/\text{Perimeter}^2$
Roundness	Roundness = $4 \cdot \text{Area}/(\pi \cdot \text{Feret}^2)$
ArEquivD	Area equivalent diameter = $\sqrt{((4/\pi) \cdot \text{Area})}$
PerEquivD	Perimeter equivalent diameter = Area/π
EquivEllAr	Equivalent ellipse area = $(\pi \cdot \text{Feret} \cdot \text{Breadth})/4$
Compactness	Compactness = $\sqrt{((4/\pi) \cdot \text{Area})}/\text{Feret}$
Solidity	Solidity = Area/Convex_Area
Concavity	Concavity = Convex_Area-Area
Convexity	Convexity = Convex_hull/Perimeter
Shape	Shape = $\text{Perimeter}^2/\text{Area}$
RFactor	RFactor = Convex_Hull /$(\text{Feret} \cdot \pi)$
ModRatio	Modification ratio = $(2 \cdot \text{MinR})/\text{Feret}$
Sphericity	Sphericity = MinR/MaxR
ArBBox	Area of the bounding box along the feret diameter = $\text{Feret} \cdot \text{Breadth}$
Rectang	Rectangularity = Area/ArBBox

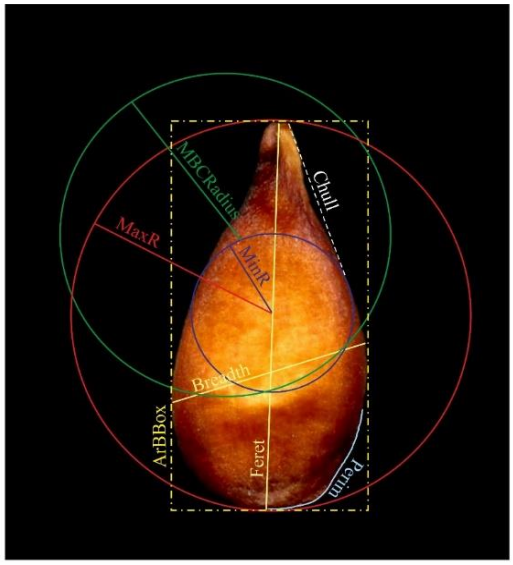

Fig. 5 Graphical representation of principal morphometric parameters measured on each seed (see Tab. 2).

3. Results

The first comparison among the 65 ancient *P. communis* local varieties from Sardinia was executed, achieving a 38.8% cross-validation (Fig. 6).

The first analysis showed a high classification within each varieties: Belgamotta (100%): Meli (72,9%); Sa Maddalena (71,7%); Piringino di Giugno (68,0%); Santa Barbara (66,0%); Roma (64,9%); Alveghina (63,3%); Limoni b (62,5%); Lida (61,7%). Other varieties that showed a discriminatory power of more than 50% were: Camusina di Paegle (58,3%); Pera Mela (55%); San Giovanni Migliorata (54,9%); Vacchesa (51,0%); Laconi2 (50,8%) San Domenico (50,9%). Moreover varieties that showed a low percentage of discrimination below 10% were: Appicadorza (0%); Funtana Sones (0%); Limoni a (0%); Parena (0%); Camusina di Bonarcado (0%); Meba (0%); Buttiu de Austu (5,7%); Arriabi (7,1%) e Pira Mamoi (9,1%).

The LDA analysis, conducted to differentiate pear varieties from the catalog field of Cadriano (Bologna) showed a cross-validation of 38.1% (Fig.6). Noteworthy, of the 45 varieties analysed 12 showed a high discriminant percentage: Pero rossellini (95,9%); Martin del bosc (78,0%); Idice B (72,5%); Campigna (73,1%); Pec hams (62,4%) e Suittore (64,1%), Pera fiorenza (57,8%); Pera bianca (60%); Avalle (59.6); Per Duche (52,9%); Martin Sec (52,7%), Spadona d'inverno (51,2%); e Compigna b (50%). Moreover, varieties that showed a percentage of discrimination below 10% were: Grossa di castagnito (2,8%); Pero truvela (8,6%); Tarda (8,9%) e Dr. Guyet (9,4%).

In addition, the LDA analysis conducted on the varieties of *P. spinosa* from Sardinia showed a general cross-validated by 74.4% (Table 3; Fig. 8). Varieties with the highest rates of discrimination were:

Benetutti (95,6%) e Illorai (90%). Moreover, the variety with the lowest percentage of discriminant was Sirri (21,7%) (Table 3).

Furthermore, the LDA conducted on the two *P. communis* groups (SA and BO *P.c.*) and *P. spinosa* of Sardinia showed that these three groups are able to differentiate from each other, showing, in fact, a percentage of discrimination of 62,7% for Sardinian varieties, 68,8% for national and international varieties of Bologna catalogue field and 76,5% for the varieties of *P. spinosa* of Sardinia (Table 4; Fig. 9).

Moreover, considering *P.spinosa* which unknown group, LDA analysis showed similarities with the cultivars of Sardinia with 56,6 % cases (Table 5).

Considering the different degree of ripeness and over-ripening in Sardinia pears, LDA showed a cross-validated of 77.6% (Table 6; Fig. 10). Early-ripening pears were discriminated with a percentage of discrimination of 90.7%, intermediate varieties with of 26.4% and late varieties with a percentage of 58.2% (Table 6).

Finally, the analysis conducted for investigating the characteristic of over-ripening showed an optimal discrimination with a cross-validated 98.2% (Table 7; Fig. 11). In this case, the varieties with high over-ripening were discriminated to 96.8% and with low over-ripening to 99,2%.

4. Discussion

The LDA conducted on *P. communis* varieties from Sardinia and Bologna used in this study showed a low percentage of discrimination. This may be due to the fact that *Pyrus* has a genetic history similar to that of the *Malus* genus even in the case of the *Malus* genus, the LDA shows a low diversification of varieties within the studied collections (Kole, 2011).

Regarding the Sardinian varieties, there was good discrimination only for some ones, such as the "Belgamotta" variety. Unfortunately, the scarcity or total missing of bibliographic information does not allow us to discuss these results. Further morphological and genetic analyses could help in understanding the results obtained.

Moreover, the LDA carried out on the Bologna varieties showed a high degree of diversification for some individual cultivars, such as Pero Rossellini. In fact, in the work of Martinelli et al. 2008, "Pero Rossellini" is mentioned among the old varieties of Trentino Alto Adige. Genetic and morphometric studies based on agronomic data of "Pero Rossellini" have shown that this variety is both genetically and morphologically different from the others, supporting our results.

The LDA conducted on *P. spinosa* varieties showed a good percentage of discrimination. This may be explained by the fact that *P. spinosa* was collected in different territories of Sardinia and environmental conditions, *e.g.* tree age and growth phases, may influence phenotypic characteristics (Rotondi et al., 2003).

The results obtained through LDA, considering varieties of *P. communis* from Sardinia and Bologna and *P. spinosa* showed that *P. spinosa* ones are more closely related to Sardinian *P. communis* ancient varieties, in comparison to Bologna varieties grouping separately.

This result can be explained by the fact that some varieties of Sardinian *P.communis* have certainly originated from the populations of *P.spinosa* present in Sardinia, while the varieties of national and international *P.communis* came from different populations of *P.spinosa*.

In fact, as known *P.spinosa* represents a Wild Crop Relative (CWR), with primary gene pool, of *P.communis* and hence interfertile with it (Vincent et al., 2013).

LDA conducted considering the different degree of over-ripening of Sardinian *P. communis* varieties, showed that early and late harvested varieties were those with the highest percentage of discrimination, showing an effective correlation between the shape of the seed and the different degrees of over-ripening. In addition, the same analysis conducted considering the high maturity varieties, showed that it was possible to perfectly discriminate all varieties that present this characteristic.

This work is the first study conducted to characterise pear varieties in Sardinia based on seed morphometric data and the results obtained show that seed morphology reflects phenotypic and genotype characteristics of the varieties and how these data can be compared with genetic

analyses to shed light on the relationships between seeds morphology and characteristics of fruit.

CHAPTER 4: Characterisation of microsatellite loci in Sardinian pears (*Pyrus communis* L. and *P. spinosa* Forssk.).

1. Introduction

The cultivation of the pear trees in Sardinia has a long history originating from its spread in ancient times which is extensively documented by the historical bibliography. Pliny reminds him of 39 varieties. Aristotle exalts fruit from Sardinia, as well as other authors of antiquity (Pausania, Polibio, Diodoro) (Agabbio, 1994). In the Roman world, Virgilio, Celsus, Columella and Pliny evidence the splendour on the cultivation of pear trees in Italy and providing us with valuable indications on the cultivar then widespread and known. More than a hundred pear varieties in Sardinia are now recognized, of ancient origin with morphological and qualitative characteristics that have allowed the differentiation of a rich heritage of varieties (Agabbio et al., 1986).

However, in the centuries in Sardinia, a rich local germplasm has been differentiated (Agabbio, et al., 1986, 2015) which presents varieties with agronomic and qualitative characteristics that can be found in modern fruit groves, increasingly conditioned by competition and the difficulty of ensuring comparable income with other economic activities (Muresu et al., 1997). The importance of local cultivars lies in the high genetic variability that characterizes them and has allowed them to adapt to adverse environmental conditions over the years, in which they have however, managed to have a good yield, thus protecting populations from complete crop loss. (Hammer et al., 2003).

Despite the low yields and unsatisfactory quality of the old local pear varieties, they represent a precious source of genetic variability for many traits that are not yet exploited by current breeding programs as already done for apple trees (Liang et al., 2015). In addition, an efficient molecular characterisation of pears varieties, would be required to manage this genetic heritage by identifying clonal relationships, synonyms and homonyms, their propagation, and correct taxonomy. Microsatellite or simple sequence repetition (SSR) is omnipresent in eukaryotic genomes, thus becoming a marker of choice for both animal and plant species, due to their reproducibility, multi-allelic nature, codominant inheritance, relative abundance, and good genome coverage (Weber and Mat, 1989; Powell et al., 1996).

In recent years, the work of SSR primers focused on the varietal heritage of *Pyrus pyrophilia* Japanese, leading to a small study on the European *Pyrus* SSR varieties (Bao et al., 2007, Fernàndez-Fernàndez et al., 2006, Yamamoto et al., 2002a, b, c). Some SSRs have been standardized for pear varieties in Europe (Evans et al., 2009) in order to compare germplasm

collections. The low morphological diversity of fruits, the lack of distinctive features among species, and the high crossing potential have made it very difficult to estimate the genetic diversity of the different *Pyrus* genres.

The aim of the present study was to estimate the genetic relationship among wild and local pear varieties from Sardinia and national and international ones, using SSR markers. This molecular characterization will: identify the genetic diversity; investigate cases of homonymous and/or synonymous genotypes that are difficult to distinguish using standard morphological descriptors and increase the *Pyrus* molecular marker datasets.

2. Materials and Methods

2.1. Germplasm material, DNA extraction and SSR genotyping

A list of the 109 varieties analysed is included in Table 1. The samples including 78 local varieties from the CNR-ISPA catalogue field (Nuraxinieddu, Oristano, Sardinia) and 5 varieties from the Fo.Re.S.T.A.S catalogue field (Monte Pisanu, Bono, Sardinia). Moreover, 24 *P. spinosa* collected in Sardinia and 3 international reference cultivars ('Williams', 'Abate', 'Keiser') (Table 1).

For each variety, genomic DNA was extracted from 50mg of young freeze-dried leaves following the standard CTAB protocol (Maguire et al., 1994). Genomic DNA was quantified by Nanodrop™ ND-1000 Spectrophotometer (Thermo Scientific, Wilmington, DE, USA) and diluted to 10ng/µl.

A set of nine SSRs was chosen from the HiDRAS (High-quality Disease Resistant Apples for Sustainable Agriculture) website (http://users.unimi.it/hidras/), mainly based on their distribution across the pears genome. Forward SSR primers were labelled whit 2'-fluorescent dyes: VIC and FAM (Table 2).

The amplification of markers was performed using PCR protocol for apple cultivar as described by Liang et al. (2015). PCR was performed in a 10µl reaction mixture containing 1× reaction buffer (Applied Biosystems, Foster City, CA, USA), 1.5 mM $MgCl_2$, 0.2 mM dNTPs (Fermentas, Lithuania), 5n Meach SSR locus-specific primer,76 nM dye-labeled tag-F and unlabeled tag-R primers, 10ng genomic DNA and 0.5 U AmpliTaq Gold DNA polymerase (Applied Biosystems). The PCR reactions were carried out in a 2720 thermal cycler (Applied Biosystems) with the following amplification protocol: an initial denaturation step of 10 min at 95°C, followed by 20 cycles of 30 s at 92 °C, 90 s at 60 °C, and 60 s at 72 °C, and then 40 cycles of 15 s at 92 °C, 30 s at 45 °C, and 60 s at 72 °C, with a final extension step of 10 min at 72 °C (Fig.1).

Multi-pooling groups (MPG) of SSRs labelled with the four different fluorescent dyes were designed for SSR genotyping on an ABI PRISM 3730 DNA analyzer. SSRs were pooled by mixing PCR products labelled with different dyes in a ratio of 1:1:1:2 for VIC: FAM; 3µl of the PCR products mixture was added to 7µl of formamide containing 0.2µl of GeneScan500 LIZ size standard (Applied Biosystems). Fragments were visually analysed and scored by using Peak Scanner v.1.0 (Applied Biosystems). To monitor the reproducibility in different amplifications, three reference cultivars, ‘Abate’, ‘Kaiser’, ‘William’, were included in each single run.

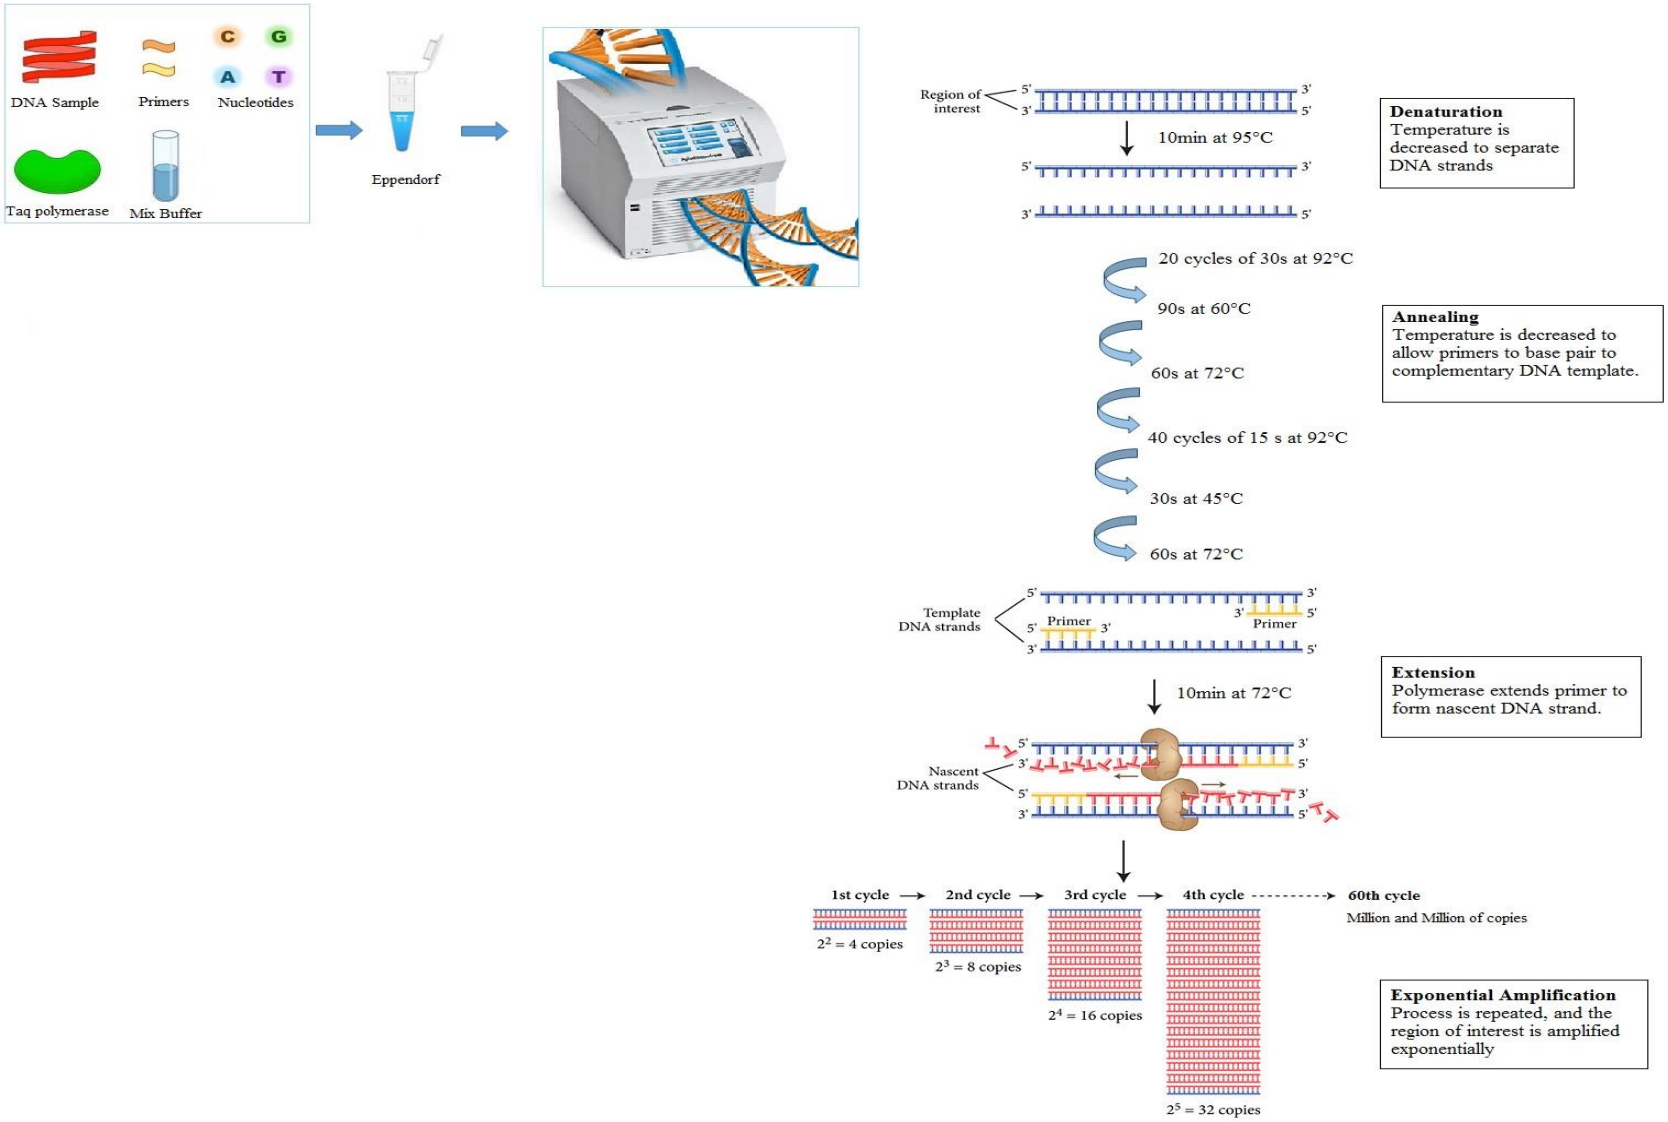

Fig.1 PCR protocol used in this study.

2.2. SSRs Marker

The PCR products were amplified using the ABI 3730 DNA analyser made available by Sant'Orsola Hospital in Bologna. To facilitate a highly parallel SSR genotyping, the products of nine SSRs were assigned to two multi-pooling groups (MPGs). The procedure consists of making two different SSR amplification products with two fluorescent dyes (VIC and FAM), then combining them with single MPG based on the range of their allele length. If on the markers panel, the two SSR alleles will be separated, without overlapping each other, the two SSRs will be strongly recommended as a multi-pooling group.

The protocol used to prepare SSR products for electrophoresis it was as follows: PCR products labelled with different fluorescent dyes were pooled in a total volume of 25 µl at a ratio of 1 : 1 : 1 : 2 for VIC: FAM, according to differences in the relative fluorescence of each fluorophore; 3 µl of PCR products mixture was added 7 µl of deionized formamide containing 0.2 µl of GeneScan500 LIZ size standard (Applied Biosystems). This multi-pooling mixture containing two different SSR amplification products was separated on a capillary electrophoresis ABI 3730 DNA sequences. Raw fragment size data were analysed using Peak Scanner Software v1.0 (Applied Biosystems) (Fig. 2), and all automated results were manually reviewed.

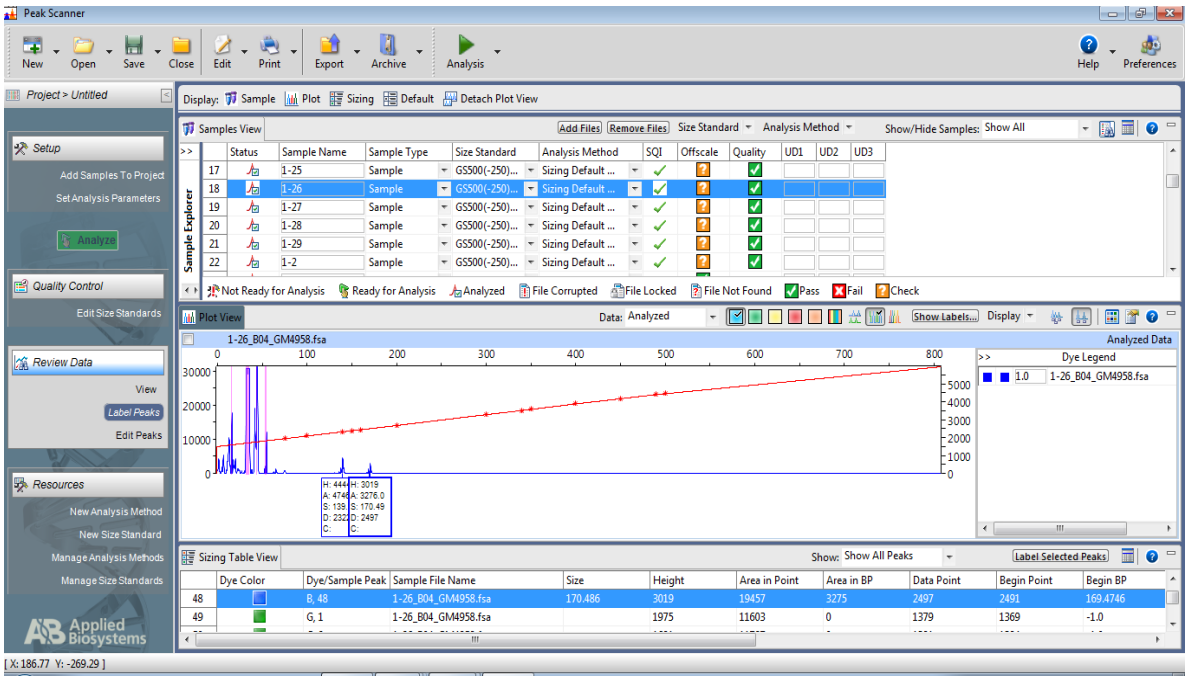

Fig. 2 Peak Scanner Software v. 1.0.

2.3. Data analysis

To investigate the different levels of polyploidy the software STRUCTURE (Pritchard et al., 2000),(https://web.stanford.edu/group/pritchardlab/structure_software/release_versions/v2.3.4 /html/structre.html) was used in a dataset formatted by 454 unique pear accesses created by Fernandez-Fernandez in 2008 and by 22 unique Sardinian pear genotype.

Moreover, through this software it was possible to detect different genetic statistical information including: the number of alleles per locus (A); the expected heterozygosity (He) and Wright's fixation index (Fst). To determine the possible presence of null alleles, the genetic uniqueness of each varieties, and to quantify redundancy, the multilocus DNA profile of all the varieties was compared pairwise using the program Cervus ver. 3.0 (Kalinowski et al., 2007) under the identity analysis with the setting of minimum number of matching loci is 15 and allow 0 mismatch. The collected data were organized in a square matrix in which the code '0' was used for allele absence and the code '1' for presence of allele (code for missing data was 9).

The genetic distance between cultivars was then calculated through the DICE coefficient (Dice 1945) by the SimQual procedure of NTSYSpc 2.0 (Rohlf 1994). The dendrogram was constructed using the unweighted pair group method average (UPGMA) clustering and drawn with NTSYSpc 2.0 program (Rohlf, 1994). To investigate the population structure using the genotype data of our dataset, a Bayesian clustering method (Pritchard et al. 2000a; Falush et al. 2003) was applied using the STRUCTURE v.2.3.4 free software.

Through this method it was possible to detect the underlying genetic population among a set of individuals genotyped at multiple markers and computes the proportion of the genome of an individual originating from each inferred population (quantitative clustering method). For the structure analysis, putative triploid varieties were removed from the dataset. Previous information was not used to define clusters. Independent runs were done by setting the number of clusters (k) from 2 to10. Each run comprised a burn-in length of 10000 followed by 100000 MCMC (Monte Carlo Markov Chain) replicates. To estimate the most likely number of clusters (k), Structure Harvester software was used (taylor0.biology.ucla.edu/structureHarvester/).

For each cluster, the varieties have been divided for Q> 0.8 compared to the others that are to be assigned to a cluster only for a greater Q, but that are not unequivocally.

Subsequently, the statistic Δk was calculated to identify the number of clusters (k), using the Structure Harvester software (taylor0.biology.ucla.edu/structureHarvester/), using a zip file analysis with all the simulation results for a structure hypothesis from two to ten populations. In addition, subsequently, each of the k groups was analysed individually by STRUCTURE

v.2.3.4. (Pritchard et al., 2000). Finally, for each of the clusters, the fixation index was calculated.

3. Results

We created a dataset for Sardinian pear varieties composed of 83 local varieties of *P. communis*, 24 *P. spinosa* and three international reference cultivars ("William", "Kaiser" and "Abate"), (Table 1). The nine SSR markers showed a clear and easy readable peak amplification. Peaks evaluation of the varieties used as references has allowed ensuring that the SSRs used have been reliable markers to assess the diversity of pear germplasm as confirmed by Seich et al. (2012). Thus, a total of nine polymorphic loci were statistically analysed, giving a total of 194 alleles for 109 varieties, with a minimum of 14 (CH04e03) to a maximum of 26 different alleles (CH01d09) (Table 2). In addition, the analysis of allelic frequencies within the locus examined showed uneven distribution (low or high) with values between 0.006 (CH01d09 and Ch01f07a) and 0.651 (CH04e03) (Table 2). For all the SSR loci studied, 15 specific rare alleles were identified with a minimum of two (EMPc11, EMPc117) to maximum 17 (CH01f07a). Were identified 78 varieties with three alleles in at least one locus, of which 20 varieties with three alleles in two loci, six varieties with three alleles in three loci, 10 varieties with three alleles in four loci, five varieties with three alleles in five loci and two varieties with three alleles in six loci. The remaining 36 varieties have presented only one locus with three alleles (Table 3). After a careful examination of our dataset, we found three varieties with four alleles in a single locus: "De Puleu", "Buttidu de Austu" and "Mela". In our work, the number of alleles present in each locus and the range of values in which they are found differs from that found in the literature (Table 4). The overall allelic diversity have showed by the set of 9 SSRs used revealed a high genetic variation in the estimated germplasm. Respect to other large-scale studies of the genetic diversity of pear, the average number of alleles per locus (21.5) was different (9.4) than that reported in the literature (Table 3). Comparison of SSR profiles have showed four groups of diploid varieties that had the same SSR profile, the size of these groups consisting of two varieties with different names have showed the presence of homonymous in our dataset. In addition, one of these groups was constituted of a variety used as reference "William" and the variety called "Reale" in our dataset. Cluster analysis carried out on the Sardinian dataset has allowed identifying different homonymous varieties: "Cazzone Ainu" with "Bragamotta"; "Enosa" with "E' Donna"; "Reale" with "William" and "Acueghina" with "Bau" it is confirming the comparison of SSR profiles (Fig. 3). Furthermore, the varieties "Vacchesa" and "Pira

Ortine"; "Laconi2" and "Camusina precoce"; "White" and "Mamoi"; "Armungesa" and "Di Mulargia" have discriminated for less than 10 alleles placed in different loci (Fig. 3, Table 5).

In addition, the analysis showed that the *P.communis* group is phylogenetically separated from that of *P. spinosa* although , the varieties of *P.communis* "Pira cona arrubia" and "Pira di urzulè" were resulted phylogenetically closer to varieties of *P. spinosa* respect to other *P.communis* in the data set.

The datasets of international varieties has presented numerous cases of homonymies among the varieties (Fig. 4). Moreover, it has also been shown that there are no great relationships between genotypes of Sardinian and international varieties.

The variety called "San Domenico" in Sardinian dataset showed a single difference allele (110) located on the same locus (CH3d12) with "Beur-Giffard" by Fernàndez-Fernàndez (106), showing a 100% likeness. An important result of the alignment of the two datasets confirmed the homonymies present in Sardinian varieties and the phylogenetical position of *P.spinosa*.

Another, showed a correlation between a small part of Sardinian and Japanese varieties (Fig. 4). The analysis of the allelic frequencies of the entire dataset, including Sardinian and international varieties, showed how many alleles of the Sardinian are in common with the European varieties. Structure Harvester software was used to conducted structure analysis on 449 unique pear genotypes, (including 22 Sardinian single diploid genotypes and a total of 454 international genotypes) showed the formation of four distinct genetic groups. Sardinian varieties were included into a single group, showing a 0.95 Q value (Fig. 5). A second group enclosed the Japanese *P. pyrifolia* varieties (Q = 0.01), a third group including, late varieties (Q= 0.02) and a fourth group composed of the all most famous varieties used in breeding (Q = 0.02) (Fig. 5).

Although the differences between the groups did not show very large values, they were still statistically valid, the level of differentiation between these four groups has been very evident for Sardinian varieties, which unequivocally were distinguished from all others.

The F_{st} was calculated for each single groups: group one had 0.0015; group two 0.3981; group three 0.1232; and group four 0.2322. The value of the fixing index (F_{st}) for each gene groups was found to be very low.

As far as, *He*, got higher values with group one values of 0.834; for group two of 0.6305; for group three of 0.7069 and for group four of 0.6308. Evanno's statistical analysis Δk has shown unequivocally k = 4 ($\Delta k = 150$) as the most likely stratification level of the population (Fig. 6). Finally, the Baterplot has charted clearly shows the presence of four distinct gene groups (Fig. 7), confirming the hypothesis of k = 4.

Table 2. Allele frequency of 9 SSRs in Sardinian *Pyrus* germplasm with 454 varieties. Rare alleles are indicated in bold, unique alleles are evidence by underlining.

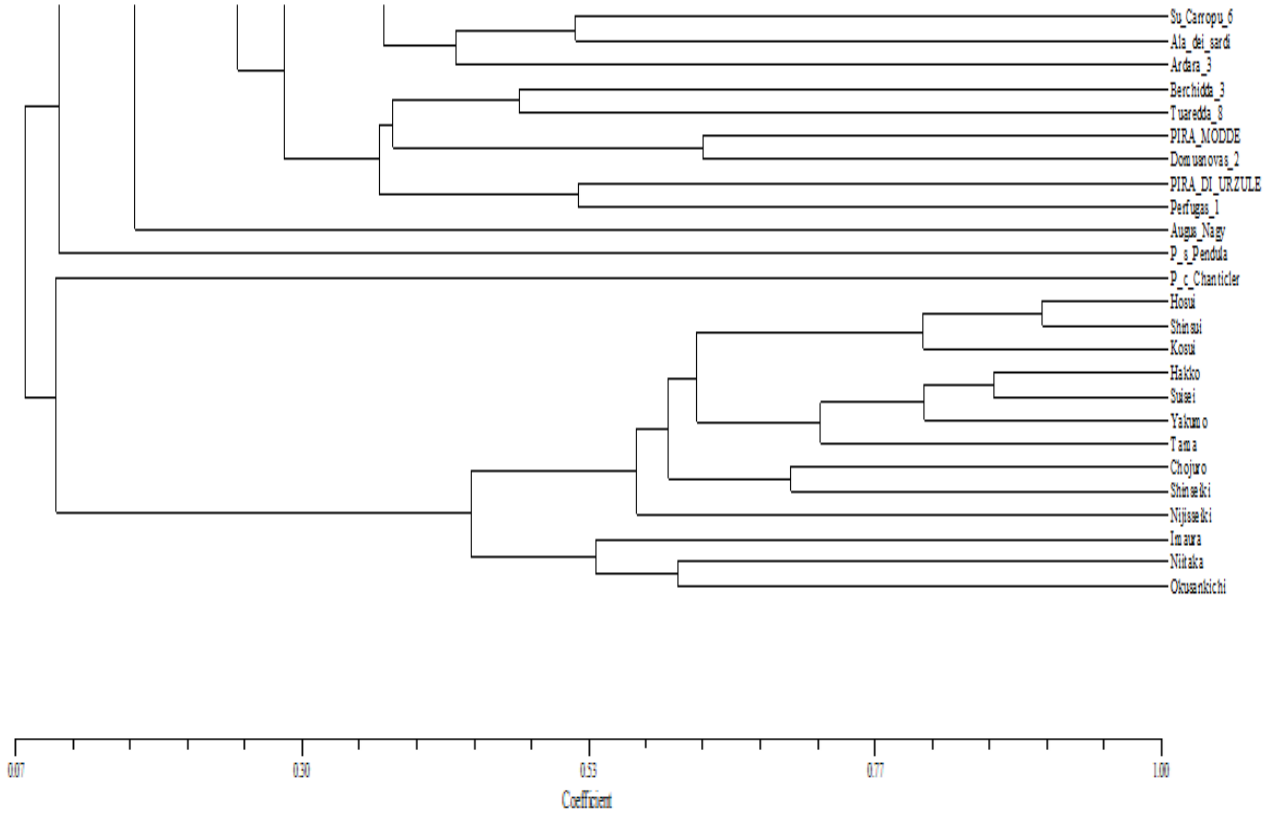

Fig. 4 Dendrogram of 625 pear varieties from international germplasm based on Cophenetic Correlation Coefficient calculated from the allele frequencies of 194 alleles found in 9 SSR loci. In the rectangles, the homonymies found in the international dataset of *Pyrus* accessions.

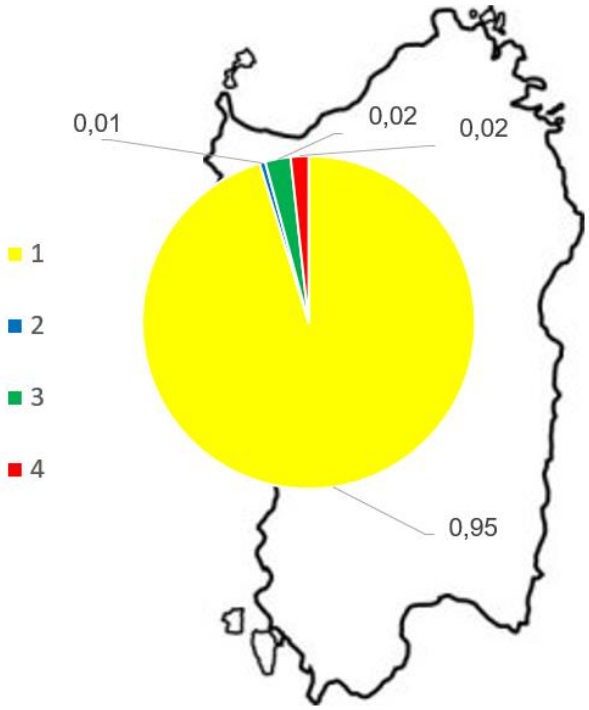

Fig. 5. Distribution of Q values related to the Cluster of the varieties of Sardinia. (1): Sardinian varieties; (2): Japanese varieties; (3): late varieties; (4): the most famous varieties used in breeding**.**

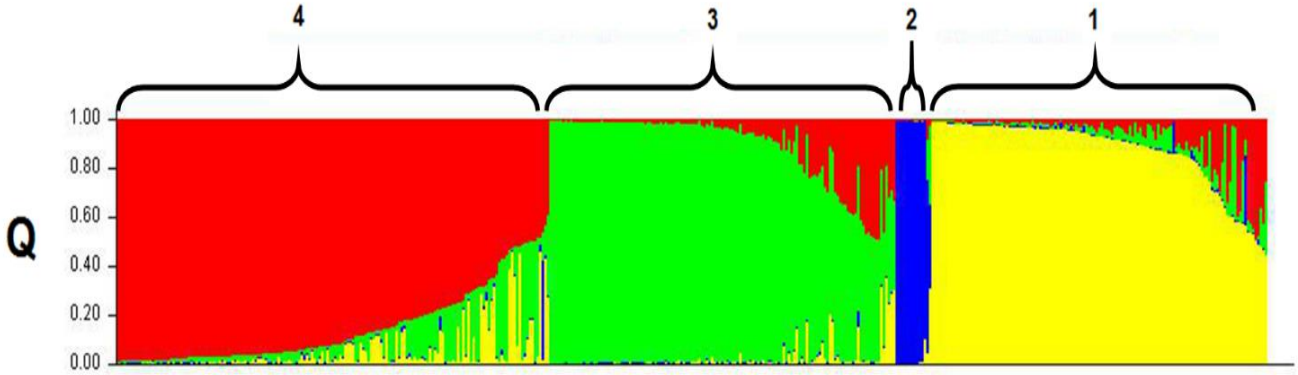

Fig. 6. Groups identified in the first round structure analysis. 1,2,3,4 corresponding a number of cluster. In yellow Sardinian varieties; in blue Japanese varieties; in green late varieties; in red the most famous varieties used in breeding**.**

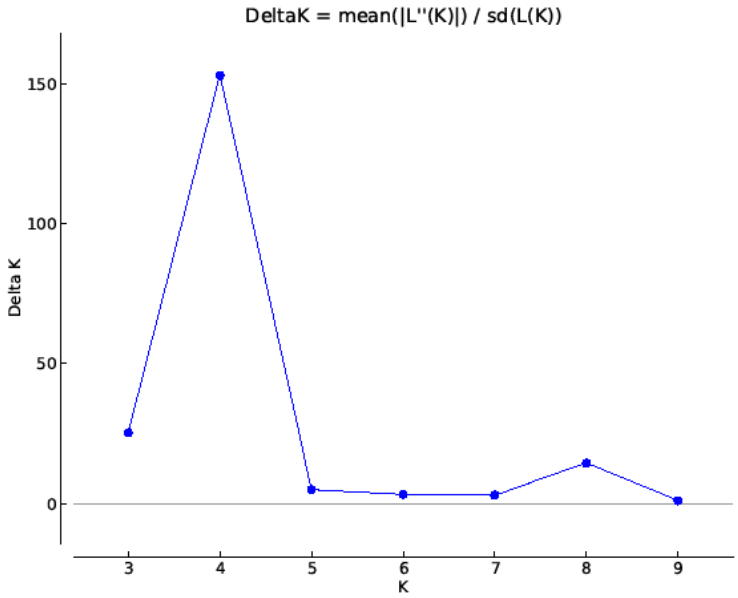

Fig. 7 Slope rate change estimates of the log probability curve (Δk) calculated according to Evanno et al. (2005) plotted against number of cluster (k).

4. Discussion.

The nine SSR markers used for our the analysis were selected on the basis of the work carried out by Seih et al. (2012), in which eight markers for apple and two for pear were used. The transferability of SSR information from a species to a related second species has been demonstrated abundantly in the work of Pierantoni et al., (2004). Reproducibility and coherence in amplified peak readings in the references "William", "Keizer" and "Abate" have allowed ensuring that SSRs used in this work are reliable markers of the diversity of pear germplasm.

The 15 alleles recognized as unique were present in a single genotype, indicating a substantial level of allelic diversity ever used in breeding programs. The presence of a few rare alleles is reflected in the structure, in fact there is a single large group that encloses all diploids.

The use of reliable SSRs is essential for effective differentiation of cultivars and for establishing genetic relationships such as in the case of identification of homonymies and synonymies. In fact, the case of synonymies between Sardinian varieties called "Reale" and the "William" reference, is definitely not due to an error in reading the peaks but may be explained by the fact the variety called in Sardinia "Reale" is surely the same variety called "William" on international data set.

The overall allelic diversity shown by the set of nine SSRs used revealed genetic variability in pear germplasm, especially as regards the varieties of *P. communis* in comparison to *P. spinosa*. Moreover, the phylogenetic proximity between the varieties of *P.communis* "Pira di Urzulè" and "Pira cona arrubia" with the population of *P.spinosa* can be explained by the fact that these varieties may originate from hybridization with the populations of *P. spinosa* present in the territory.

In fact, the hybridizations between these two species are known (Vincent et al., 2013).

The high number of triploids in Sardinian varieties can be explained by the fact that *Pyrus* is an allotetraploid species, so the marker might have amplified another locus. Additionally, the identification of four homonymies in the Sardinian varieties emphasized the importance of testing germplasm referee's collections with powerful tools such as molecular markers to avoid real repetitions and eliminate any duplications that may be present.

Thanks to the existence of a large dataset created by Fernàdez-Fernàndez et al. (2006), that comprised *Pyrus*'s international varieties, it has been possible to compare these varieties with our dataset, thus increasing the availability of usable data for future analysis.

The alignment of the two datasets was possible because the same markers were used. In addition, the use of the same Dice index has allowed us to certify the synonymies present in the cluster analysis. In fact, this index allows establishing the synonymies based on the coexistence of the bands and not for the co-absence (Dice, 1945).

Fernàndes-Fernàndez dataset's reliability, on which we have made no modification, is confirmed by the presence of the same synonymies found in Sardinia's varieties, once the two datasets have been merged.

The only homonymy found among the varieties of Sardinia and the international varieties is represented by the variety “San Domenico” and “Beur-Giffard” for international varieties. In future a pomological comparison would be an excellent methodology for the confirmation of molecular data.

The confusion generated between few Japanese and Sardinian varieties could be related to a play of weights, elongation, and shortening of the alleles, which could have the same molecular weight.

Moreover, the fact that many of the alleles present in Sardinia's varieties are also present in European varieties confirms the hypothesis of germplasm exchange between Italy and France that probably occurred during the Sardinian-Piedmont reign (1720-1861).

Regarding Structural Analysis, the value of Q found in the group of Sardinian varieties indicates that there is virtually no genetic flow from the other groups.

The very low F_{st} observed in all four groups, indicates that genetic variability is not massively linked to the structure of the population analysed. In fact, although there is a difference between the statistically valid, groups we are in a fairly homogeneous pool gene.

The high *He*, found in all four groups was predictable, considering the two species compatibility (pear and apple).

Moreover, the ΔK chart clearly shows the validity of the hypothesis that there are four distinct groups within the analyzed population, a hypothesis that is clearly confirmed by the Baterplot graphic.

5. Conclusion

The main consideration in building a data set from a very large germplasm collection is to develop reliable classification criteria. The use of the same SSR markers and the same DICE index. In addition to the confirmation of the same synonymies found in the two datasets that were compared, allowed to obtain reliable data that could be used for future work on characterization of germplasm *Pyrus.* In addition, the study of Sardinian varieties has made it possible the know a genetic diversity that is not yet investigated as an important resource that could provide the answer to the main goals of genetic improvement.

General Conclusion

Germplasm Banks' collections of local fruit varieties are still incomplete, and the gaps in these gatherings may create limitations on the options available for researchers to study and introduce new taxa into protection programs.

At the same time, many local varieties are threatened in nature by changes to their habitats, by the modernization of agricultural areas, invasive species, and climate change that may aggravate their vulnerability. The loss of old varieties typical of a territory represents for local communities not only a serious defeat from the biological, ecological and cultural point of view but also the loss of great opportunities for development.

The main goals achieved through this doctoral research were different and can be summarized in the following four points:

1. Through the morphometric analyses performed on the ancient Sardinian apples varieties it was possible to investigate the bonds between the morphology of the seeds and the color of the skin, showing the existence of a relationship that had never been described before and which represent an important starting point for future phenotypic studies on new varieties.
2. Comparison of existing genetic analysis and morphometric analysis of national and international apple varieties has made it possible to evaluate phenotypic and genotypic diversity and compare the two types of analysis, demonstrating how morphometric analysis was an important method to support molecular analyses.
3. Through the morphometric analysis carried out on ancient Sardinian pome varieties and on national and international pear varieties, it has been possible to characterize the different varieties and to demonstrate how Sardinian *P.spinosa* varieties are more closely related to local varieties of *P.communis* than to the ones provided by the University of Bologna, which clustered in a distinct group. Moreover, through the analyses carried out on pear fruit core browning, it was possible to establish that early and late harvested varieties better describe the correlation between fruit maturation and seed morphology.
4. Finally, through the genetic analysis of Sardinian local pear varieties and national and international ones, it was possible to investigate a genes pool that had never been subjected to analysis. Moreover, it was possible to shed light on cases of synonymy and homonymy discovering also new alleles useful for future breeding programs.

In conclusion, the research carried out during the PhD program allowed to build-up a morphometric and genetic data set of *Malus* and *Pyrus* varieties, increasing the knowledge on these varieties and laying the foundations for future studies.

Acknowledgements

In priimis un sentito ringraziamento al Tutor di questa tesi Prof Gianluigi Bacchetta per la capacità che ha dimostrato di stimolare il mio interesse per l'argomento qui discusso, per avermi mostrato aspetti relativi allo stesso che senza di lui probabilmente avrei ignorato, e infine, per la sua pazienza, e per la fiducia in me e l'entusiasmo che mi ha trasmesso per questo lavoro.

Un sentito ringraziamento ai Cotutor Oscar e Guy ed in particolare a Mariano per il lavoro svolto in questi anni, per i confronti costruttivi, gli approfondimenti, gli stimoli, gli spunti forniti alla tesi, oltre che per la sua disponibilità.

Ringrazio inoltre tutti i colleghi del CCB. Un singero Grazie a Giuseppe, per l'esempio che mi ha dato e che considero molto importante per la mia formazione, di come sia possibile amare e far amare lo studio e la conoscenza di una materia non sempre facile, come la Botanica, attraverso dialoghi e confronti mai banali ma anzi sempre costruttivi.

È un bagaglio importante, sia culturale che di impostazione mentale, che porterò sempre con me.

Un grazie di cuore alla collega Silvia, indiscutibile ascoltatrice e compagna di merende, che mi ha sempre saputa rasserenare e sostenere nei momenti più faticosi e nei quali non nego di aver pensato di abbandonare questo percorso.

Un profondo ringraziamento al Prof Luca Dondini e a tutto il suo team, siete stati un pilastro importante della mia formazione in questi anni di Dottorato, Grazie per non avermi fatto sentire la nostalgia di casa e per avermi insegnato come si lavora seriamente per ottenere buoni risultati.

Sentiti ringraziamenti indubiamente vanno ai miei genitori, che hanno permesso di raggiungere questo traguardo dandomi sempre opportuni consigli e non facendomi mai mancare il loro supporto, unitamente a tutti i miei fratelli, sorelle e nipoti.

Un sentito Grazie ai miei suoceri e a mio cognato Paolo voi sapete il perchè, Grazie!

Un Grazie infinito al mio compagno di vita Daniele, finalmente il traguardo è stato raggiunto e tu che mi sei sempre stato vicino, sei certamente la persona che meglio può capire come mi senta in questo momento, voglio dirti che il merito è anche tuo e voglio ringraziarti, per la pazienza che hai avuto nel sostenermi, rasserenarmi e per tutte le volte che con il tuo sorriso hai saputo far sorridere anche me.

Infine a conclusione di questo percorso di Dottorato sento il dovere e il piacere di ringraziare tutti coloro che mi hanno sostenuto, supportata e sopportata in questi tre anni a chi mi sostiene ancora e a chi purtroppo è venuto a mancare...

Grazie mille a tutti Voi!!!
